TMS570LC43x 16/32-Bit RISC Flash Microcontroller

Technical Reference Manual

Literature Number: SPNU563A
March 2018

Contents

Preface **104**

1 Introduction **106**

1.1 Designed for Safety Applications 107

1.2 Family Description 108

1.3 Endianism Considerations 111

1.3.1 TMS570: Big Endian (BE32) 111

2 Architecture **112**

2.1 Introduction 113

2.1.1 Architecture Block Diagram 113

2.1.2 Definitions of Terms 115

2.1.3 Bus Master / Slave Access Privileges 118

2.1.4 CPU Interconnect Subsystem SDC MMR Port 118

2.1.5 Interconnect Subsystem Runtime Status 119

2.1.6 Master ID to PCRx 119

2.2 Memory Organization 120

2.2.1 Memory-Map Overview 120

2.2.2 Memory-Map Table 122

2.2.3 Flash on Microcontrollers 129

2.2.4 On-Chip SRAM 134

2.3 Exceptions 139

2.3.1 Resets 139

2.3.2 Aborts 139

2.3.3 System Software Interrupts 141

2.4 Clocks 142

2.4.1 Clock Sources 142

2.4.2 Clock Domains 143

2.4.3 Low Power Modes 145

2.4.4 Clock Test Mode 146

2.4.5 Embedded Trace Macrocell (ETM-R5) 148

2.4.6 Safety Considerations for Clocks 148

2.5 System and Peripheral Control Registers 151

2.5.1 Primary System Control Registers (SYS) 151

2.5.2 Secondary System Control Registers (SYS2) 205

2.5.3 Peripheral Central Resource (PCR) Control Registers 217

3 SCR Control Module (SCM) **252**

3.1 Overview 253

3.1.1 Features 253

3.1.2 System Block Diagram 254

3.2 Module Operation 255

3.2.1 Block Diagram 255

3.2.2 Timeout Threshold Compare Block 255

3.2.3 SCM Control Block 256

3.3 How to Use SCM 257

3.3.1 How to Check the Parity Compare Logic 257

3.3.2 How to Initiate Self-test Sequence 258

Copyright © 2018, Texas Instruments Incorporated

3.3.3 How to Configure Timeout Check 259
3.4 SCM Registers 260
3.4.1 SCM REVID Register (SCMREVID) 260
3.4.2 SCM Control Register (SCMCNTRL) 261
3.4.3 SCM Compare Threshold Counter Register (SCMTHRESHOLD) 262
3.4.4 SCM Initiator Error0 Status Register (SCMIAERR0STAT) 263
3.4.5 SCM Initiator Error1 Status Register (SCMIAERR1STAT) 263
3.4.6 SCM Initiator Active Status Register (SCMIASTAT) 264
3.4.7 SCM Target Active Status Register (SCMTASTAT) 264
4 Interconnect 265
4.1 Overview 266
4.1.1 Block Diagram 266
4.2 Peripheral Interconnect Subsystem 266
4.2.1 Accessing PCRx and CRCx Slave 267
4.2.2 Accessing SDC MMR Port Slave 267
4.2.3 Accessing Other Slaves via PS_SCR_S 267
4.3 CPU Interconnect Subsystem 268
4.3.1 Slave Accessing 268
4.3.2 ECC Generation and Evaluation 269
4.3.3 Safety Diagnostic Checker 269
4.3.4 Interconnect Self-test 270
4.3.5 Interconnect Timeout 270
4.3.6 Interconnect Runtime Status 271
4.4 SDC MMR Registers 272
4.4.1 SDC Status Register (SDC_STATUS) 273
4.4.2 SDC Control Register (SDC_CONTROL) 274
4.4.3 Error Generic Parity Register (ERR_GENERIC_PARITY) 274
4.4.4 Error Unexpected Transaction Register (ERR_UNEXPECTED_TRANS) 275
4.4.5 Error Transaction ID Register (ERR_TRANS_ID) 275
4.4.6 Error Transaction Signature Register (ERR_TRANS_SIGNATURE) 276
4.4.7 Error Transaction Type Register (ERR_TRANS_TYPE) 276
4.4.8 Error User Parity Register (ERR_USER_PARITY) 277
4.4.9 Slave Error Unexpected Master ID Register (SERR_UNEXPECTED_MID) 277
4.4.10 Slave Error Address Decode Register (SERR_ADDR_DECODE) 278
4.4.11 Slave Error User Parity Register (SERR_USER_PARITY) 278
5 Power Management Module (PMM) 279
5.1 Overview 280
5.1.1 Features 280
5.1.2 Block Diagram 280
5.2 Power Domains 282
5.3 PMM Operation 283
5.3.1 Power Domain State 283
5.3.2 Default Power Domain State 283
5.3.3 Disabling a Power Domain Permanently 283
5.3.4 Changing Power Domain State 283
5.3.5 Reset Management 284
5.3.6 Diagnostic Power State Controller (PSCON) 284
5.3.7 PSCON Compare Block 284
5.4 PMM Registers 285
5.4.1 Logic Power Domain Control Register (LOGICPDPWRCTRL0) 286
5.4.2 Logic Power Domain Control Register (LOGICPDPWRCTRL1) 287
5.4.3 Power Domain Clock Disable Register (PDCLKDISREG) 288
5.4.4 Power Domain Clock Disable Set Register (PDCLKDISSETREG) 289

Copyright © 2018, Texas Instruments Incorporated

5.4.5 Power Domain Clock Disable Clear Register (PDCLKDISCLRREG) ... 290
5.4.6 Logic Power Domain PD2 Power Status Register (LOGICPDPWRSTAT0) ... 291
5.4.7 Logic Power Domain PD3 Power Status Register (LOGICPDPWRSTAT1) ... 292
5.4.8 Logic Power Domain PD4 Power Status Register (LOGICPDPWRSTAT2) ... 293
5.4.9 Logic Power Domain PD5 Power Status Register (LOGICPDPWRSTAT3) ... 294
5.4.10 Logic Power Domain PD6 Power Status Register (LOGICPDPWRSTAT4) ... 295
5.4.11 Global Control Register 1 (GLOBALCTRL1) ... 296
5.4.12 Global Status Register (GLOBALSTAT) ... 297
5.4.13 PSCON Diagnostic Compare Key Register (PRCKEYREG) ... 297
5.4.14 LogicPD PSCON Diagnostic Compare Status Register 1 (LPDDCSTAT1) ... 298
5.4.15 LogicPD PSCON Diagnostic Compare Status Register 2 (LPDDCSTAT2) ... 299
5.4.16 Isolation Diagnostic Status Register (ISODIAGSTAT) ... 300

6 I/O Multiplexing and Control Module (IOMM) ... 301

6.1 Overview ... 302
6.2 Main Features of I/O Multiplexing Module (IOMM) ... 302
6.3 Control of Multiplexed Outputs ... 302
6.4 Control of Multiplexed Inputs ... 303
6.5 Control of Special Multiplexed Options ... 312
6.5.1 Control of SDRAM Clock (EMIF_CLK) ... 314
6.5.2 Control for other EMIF Outputs ... 314
6.5.3 Control of Ethernet Controller Mode ... 314
6.5.4 Control of ADC Trigger Events ... 314
6.5.5 Control for ADC Event Trigger Signal Generation from ePWMx Modules ... 315
6.5.6 Control for Generating Interrupt Upon External Fault Indication to N2HETx ... 318
6.5.7 Control for Synchronizing Time Bases for All ePWMx Modules ... 320
6.5.8 Control for Synchronizing all ePWMx Modules to N2HET1 Module Time-Base ... 320
6.5.9 Control for Input Connections to ePWMx Modules ... 321
6.5.10 Control for Input Connections to eCAPx Modules ... 322
6.5.11 Control for Input Connections to eQEPx Modules ... 323
6.5.12 Selecting GIO Port for External DMA Request ... 325
6.5.13 Temperature Sensor Selection ... 326
6.6 Safety Features ... 327
6.6.1 Locking Mechanism for Memory-Mapped Registers ... 327
6.6.2 Error Conditions ... 327
6.7 IOMM Registers ... 328
6.7.1 REVISION_REG: Revision Register ... 328
6.7.2 BOOT_REG: Boot Mode Register ... 329
6.7.3 KICK_REG0: Kicker Register 0 ... 330
6.7.4 KICK_REG1: Kicker Register 1 ... 330
6.7.5 ERR_RAW_STATUS_REG: Error Raw Status / Set Register ... 331
6.7.6 ERR_ENABLED_STATUS_REG: Error Enabled Status / Clear Register ... 332
6.7.7 ERR_ENABLE_REG: Error Signaling Enable Register ... 333
6.7.8 ERR_ENABLE_CLR_REG: Error Signaling Enable Clear Register ... 334
6.7.9 FAULT_ADDRESS_REG: Fault Address Register ... 334
6.7.10 FAULT_STATUS_REG: Fault Status Register ... 335
6.7.11 FAULT_CLEAR_REG: Fault Clear Register ... 336
6.7.12 PINMMRnn: Output Pin Multiplexing Control Registers ... 336
6.7.13 PINMMRnn: Input Pin Multiplexing Control Registers ... 337
6.7.14 PINMMRnn: Special Functionality Multiplexing Control Registers ... 337

7 F021 Level 2 Flash Module Controller (L2FMC) ... 338

7.1 Overview ... 339
7.1.1 Features ... 339
7.1.2 Definition of Terms ... 339

Copyright © 2018, Texas Instruments Incorporated

7.1.3 F021 Flash Tools 340
7.2 Default Flash Configuration 340
7.3 EEPROM Emulation Support 340
7.4 SECDED 341
7.4.1 SECDED Initialization 341
7.4.2 ECC Encoding 341
7.4.3 Syndrome Table: Decode to Bit in Error 343
7.4.4 Syndrome Table: An Alternate Method 344
7.5 Memory Map 345
7.5.1 Location of Flash ECC Bits 345
7.5.2 OTP Memory 346
7.6 Power On, Power Off Considerations 350
7.6.1 Error Checking at Power On 350
7.6.2 Flash Integrity at Power Off 350
7.7 Emulation and SIL3 Diagnostic Modes 350
7.7.1 System Emulation 350
7.7.2 Diagnostic Mode 350
7.7.3 Diagnostic Mode Summary 352
7.7.4 SECDED Software Diagnostic 353
7.7.5 Read Margin 353
7.8 Parameter Overlay Module (POM) 353
7.8.1 Example Procedure to Configure the POM 353
7.9 Summary of L2FMC Errors 354
7.10 Flash Control Registers 355
7.10.1 Flash Read Control Register (FRDCNTL) 356
7.10.2 Read Margin Control Register (FSPRD) 357
7.10.3 EEPROM Error Correction Control Register (EE_FEDACCTRL1) 358
7.10.4 Flash Port A Error and Status Register (FEDAC_PASTATUS) 359
7.10.5 Flash Port B Error and Status Register (FEDAC_PBSTATUS) 360
7.10.6 Flash Global Error and Status Register (FEDAC_GBLSTATUS) 361
7.10.7 Flash Error Detection and Correction Sector Disable Register (FEDACSDIS) 362
7.10.8 Primary Address Tag Register (FPRIM_ADD_TAG) 363
7.10.9 Duplicate Address Tag Register (FDUP_ADD_TAG) 363
7.10.10 Flash Bank Protection Register (FBPROT) 364
7.10.11 Flash Bank Sector Enable Register (FBSE) 364
7.10.12 Flash Bank Busy Register (FBBUSY) 365
7.10.13 Flash Bank Access Control Register (FBAC) 365
7.10.14 Flash Bank Power Mode Register (FBPWRMODE) 366
7.10.15 Flash Bank/Pump Ready Register (FBPRDY) 367
7.10.16 Flash Pump Access Control Register 1 (FPAC1) 368
7.10.17 Flash Module Access Control Register (FMAC) 369
7.10.18 Flash Module Status Register (FMSTAT) 370
7.10.19 EEPROM Emulation Data MSW Register (FEMU_DMSW) 372
7.10.20 EEPROM Emulation Data LSW Register (FEMU_DLSW) 372
7.10.21 EEPROM Emulation ECC Register (FEMU_ECC) 373
7.10.22 Flash Lock Register (FLOCK) 373
7.10.23 Diagnostic Control Register (FDIAGCTRL) 374
7.10.24 Raw Address Register (FRAW_ADDR) 375
7.10.25 Parity Override Register (FPAR_OVR) 376
7.10.26 Reset Configuration Valid Register (RCR_VALID) 377
7.10.27 Crossbar Access Time Threshold Register (ACC_THRESHOLD) 377
7.10.28 Flash Error Detection and Correction Sector Disable Register 2 (FEDACSDIS2) 378
7.10.29 Lower Word of Reset Configuration Read Register (RCR_VALUE0) 379

Copyright © 2018, Texas Instruments Incorporated

7.10.30 Upper Word of Reset Configuration Read Register (RCR_VALUE1) 379
7.10.31 FSM Register Write Enable Register (FSM_WR_ENA) 380
7.10.32 EEPROM Emulation Configuration Register (EEPROM_CONFIG) 380
7.10.33 FSM Sector Register 1 (FSM_SECTOR1) 381
7.10.34 FSM Sector Register 2 (FSM_SECTOR2) 381
7.10.35 Flash Bank Configuration Register (FCFG_BANK) 382
7.11 POM Control Registers 383
7.11.1 POM Global Control Register (POMGLBCTRL) 383
7.11.2 POM Revision ID Register (POMREV) 384
7.11.3 POM Flag Register (POMFLG) 384
7.11.4 POM Region Start Address Register (POMPROGSTARTx) 385
7.11.5 POM Overlay Region Start Address Register (POMOVLSTARTx) 385
7.11.6 POM Region Size Register (POMREGSIZEx) 386
8 Level 2 RAM (L2RAMW) Module 387
8.1 Overview 388
8.2 Module Operation 388
8.2.1 RAM Memory Map 388
8.2.2 Safety Features 389
8.2.3 L2RAMW Auto-Initialization 392
8.2.4 Trace Module Support 392
8.2.5 Emulation/Debug Mode Behavior 392
8.2.6 Diagnostic Test Procedure 392
8.3 Control and Status Registers 393
8.3.1 L2RAMW Module Control Register (RAMCTRL) 393
8.3.2 L2RAMW Error Status Register (RAMERRSTATUS) 395
8.3.3 L2RAMW Diagnostic Data Vector High Register (DIAG_DATA_VECTOR_H) 398
8.3.4 L2RAMW Diagnostic Data Vector Low Register (DIAG_DATA_VECTOR_L) 398
8.3.5 L2RAMW Diagnostic ECC Vector Register (DIAG_ECC) 399
8.3.6 L2RAMW RAM Test Mode Control Register (RAMTEST) 400
8.3.7 L2RAMW RAM Address Decode Vector Test Register (RAMADDRDEC_VECT) 401
8.3.8 L2RAMW Memory Initialization Domain Register (MEMINIT_DOMAIN) 402
8.3.9 L2RAMW Bank to Domain Mapping Register0 (BANK_DOMAIN_MAP0) 403
8.3.10 L2RAMW Bank to Domain Mapping Register1 (BANK_DOMAIN_MAP1) 404
9 Programmable Built-In Self-Test (PBIST) Module 405
9.1 Overview 406
9.1.1 Features of PBIST 406
9.1.2 PBIST vs. Application Software-Based Testing 406
9.1.3 PBIST Block Diagram 406
9.2 RAM Grouping and Algorithm 407
9.3 PBIST Flow 408
9.3.1 PBIST Sequence 409
9.4 Memory Test Algorithms on the On-chip ROM 411
9.5 PBIST Control Registers 412
9.5.1 RAM Configuration Register (RAMT) 413
9.5.2 Datalogger Register (DLR) 414
9.5.3 PBIST Activate/Clock Enable Register (PACT) 415
9.5.4 PBIST ID Register 416
9.5.5 Override Register (OVER) 417
9.5.6 Fail Status Fail Register (FSRF0) 418
9.5.7 Fail Status Count Registers (FSRC0 and FSRC1) 419
9.5.8 Fail Status Address Registers (FSRA0 and FSRA1) 420
9.5.9 Fail Status Data Registers (FSRDL0 and FSRDL1) 421
9.5.10 ROM Mask Register (ROM) 422

Copyright © 2018, Texas Instruments Incorporated

9.5.11 ROM Algorithm Mask Register (ALGO) 423
9.5.12 RAM Info Mask Lower Register (RINFOL) 424
9.5.13 RAM Info Mask Upper Register (RINFOU) 425
9.6 PBIST Configuration Example 426
9.6.1 Example 1 : Configuration of PBIST Controller to Run Self-Test on DCAN1 RAM 426
9.6.2 Example 2 : Configuration of PBIST Controller to Run Self-Test on ALL RAM Groups 427
10 Self-Test Controller (STC) Module 428
10.1 General Description 429
10.1.1 Self-Test Controller Features 429
10.1.2 Terminology 430
10.1.3 STC Block Diagram 430
10.2 STC Module Assignments 436
10.3 STC Programmers Flow 437
10.4 Application Self-Test Flow 438
10.4.1 STC Module Configuration 438
10.4.2 Context Saving - CPU 438
10.4.3 Entering CPU Idle Mode 439
10.4.4 Entering nHET Idle Mode 439
10.4.5 Self-Test Completion and Error Generation 439
10.5 STC1 Segment 0 (CPU) Test Coverage and Duration 441
10.6 STC1 Segment 1 (µSCU) Test Coverage and Duration 444
10.7 STC2 (nHET) Test Coverage and Duration 444
10.8 STC Control Registers 446
10.8.1 STC Global Control Register 0 (STCGCR0) 447
10.8.2 STC Global Control Register 1 (STCGCR1) 448
10.8.3 Self-Test Run Timeout Counter Preload Register (STCTPR) 449
10.8.4 STC Current ROM Address Register - CORE1 (STCCADDR1) 450
10.8.5 STC Current Interval Count Register (STCCICR) 450
10.8.6 Self-Test Global Status Register (STCGSTAT) 451
10.8.7 Self-Test Fail Status Register (STCFSTAT) 452
10.8.8 CORE1 Current MISR Registers (CORE1_CURMISR[3:0]) 453
10.8.9 CORE2 Current MISR Registers (CORE2_CURMISR[3:0]) 454
10.8.10 Signature Compare Self-Check Register (STCSCSCR) 455
10.8.11 STC Current ROM Address Register - CORE2 (STCCADDR2) 455
10.8.12 STC Clock Prescalar Register (STCCLKDIV) 456
10.8.13 Segment Interval Preload Register (STCSEGPLR) 457
10.9 STC Configuration Example 458
10.9.1 Example: STC1 Self-Test Run 458
10.10 Self-Test Controller Diagnostics 459
11 System Memory Protection Unit (NMPU) 460
11.1 Overview 461
11.1.1 Features 461
11.1.2 Safety Diagnostic 461
11.1.3 Block Diagram 462
11.2 Module Operation 463
11.2.1 Functional Mode 463
11.2.2 Diagnostic Mode 465
11.2.3 Functional Fail Safe 465
11.3 How to Use NMPU 466
11.3.1 How to Use NMPU in Functional Mode 466
11.3.2 How to Use Diagnostics 468
11.4 NMPU Registers 471
11.4.1 MPU Revision ID Register (MPUREV) 472

Copyright © 2018, Texas Instruments Incorporated

11.4.2 MPU Lock Register (MPULOCK) 472
11.4.3 MPU Diagnostics Control Register (MPUDIAGCTRL) 473
11.4.4 MPU Diagnostic Address Register (MPUDIAGADDR) 474
11.4.5 MPU Error Status Register (MPUERRSTAT) 474
11.4.6 MPU Error Address Register (MPUERRADDR) 476
11.4.7 MPU Control Register 1 (MPUCTRL1) 476
11.4.8 MPU Control Register 2 (MPUCTRL2) 477
11.4.9 MPU Type Register (MPUTYPE) 478
11.4.10 MPU Region Base Address Register (MPUREGBASE) 479
11.4.11 MPU Region Size and Enable Register (MPUREGSENA) 479
11.4.12 MPU Region Access Control Register (MPUREGACR) 481
11.4.13 MPU Region Number Register (MPUREGNUM) 482

12 Error Profiling Controller (EPC) 483
12.1 Overview 484
12.2 Module Operation 484
12.2.1 Uncorrectable Fault Operation 485
12.2.2 Correctable Fault Operation 485
12.3 How to Use EPC 487
12.3.1 Functional Mode 487
12.3.2 CAM Diagnostic Mode 488
12.4 EPC Control Registers 488
12.4.1 EPC REVID Register (EPCREVID) 489
12.4.2 EPC Control Register (EPCCNTRL) 490
12.4.3 Uncorrectable Error Status Register (UERRSTAT) 491
12.4.4 EPC Error Status Register (EPCERRSTAT) 492
12.4.5 FIFO Full Status Register (FIFOFULLSTAT) 493
12.4.6 IP Interface FIFO Overflow Status Register (OVRFLWSTAT) 494
12.4.7 CAM Index Available Status Register (CAMAVAILSTAT) 494
12.4.8 Uncorrectable Error Address Register n (UERR_ADDR) 495
12.4.9 CAM Content Update Register n (CAM_CONTENT) 495
12.4.10 CAM Index Registers (CAM_INDEX[0-7]) 496

13 CPU Compare Module for Cortex-R5F (CCM-R5F) 497
13.1 Overview 498
13.1.1 Main Features 498
13.1.2 Block Diagram 498
13.2 Module Operation 499
13.2.1 CPU/VIM Output Compare Diagnostic 500
13.2.2 CPU Input Inversion Diagnostic 504
13.2.3 Checker CPU Inactivity Monitor 505
13.2.4 Power Domain Inactivity Monitor 507
13.2.5 Operation During CPU Debug Mode 507
13.3 Control Registers 507
13.3.1 CCM-R5F Status Register 1 (CCMSR1) 508
13.3.2 CCM-R5F Key Register 1 (CCMKEYR1) 509
13.3.3 CCM-R5F Status Register 2 (CCMSR2) 510
13.3.4 CCM-R5F Key Register 2 (CCMKEYR2) 511
13.3.5 CCM-R5F Status Register 3 (CCMSR3) 512
13.3.6 CCM-R5F Key Register 3 (CCMKEYR3) 513
13.3.7 CCM-R5F Polarity Control Register (CCMPOLCNTRL) 513
13.3.8 CCM-R5F Status Register 4 (CCMSR4) 514
13.3.9 CCM-R5F Key Register 4 (CCMKEYR4) 515
13.3.10 CCM-R5F Power Domain Status Register 0 (CCMPDSTAT0) 516

14 Oscillator and PLL 517

Copyright © 2018, Texas Instruments Incorporated

14.1 Introduction 518
14.1.1 Features 518
14.2 Quick Start 519
14.3 Oscillator 520
14.3.1 Oscillator Implementation 521
14.3.2 Oscillator Enable 521
14.3.3 Oscillator Disable 521
14.4 Low Power Oscillator and Clock Detect (LPOCLKDET) 522
14.4.1 Clock Detect 522
14.4.2 Behavior on Oscillator Failure 522
14.4.3 Recovery from Oscillator Failure 523
14.4.4 LPOCLKDET Enable 523
14.4.5 LPOCLKDET Disable 524
14.4.6 Trimming the HF LPO Oscillator 524
14.5 PLL 525
14.5.1 Modulation 527
14.5.2 PLL Output Control 528
14.5.3 Behavior on PLL Fail 531
14.5.4 Recovery from a PLL Failure 532
14.5.5 PLL Modulation Depth Measurement 533
14.5.6 PLL Frequency Measurement Circuit 533
14.5.7 PLL2 533
14.6 PLL Control Registers 534
14.6.1 PLL Modulation Depth Measurement Control Register (SSWPLL1) 535
14.6.2 SSW PLL BIST Control Register 2 (SSWPLL2) 536
14.6.3 SSW PLL BIST Control Register 3 (SSWPLL3) 537
14.7 Phase-Locked Loop Theory of Operation 538
14.7.1 Phase-Frequency Detector 538
14.7.2 Charge Pump and Loop Filter 539
14.7.3 Voltage-Controlled Oscillator 539
14.7.4 Frequency Modulation 540
14.8 Programming Example 540
15 Dual-Clock Comparator (DCC) Module 542
15.1 Introduction 543
15.1.1 Main Features 543
15.1.2 Block Diagram 543
15.2 Module Operation 544
15.2.1 Continuous Monitoring Mode 544
15.2.2 Single-Shot Measurement Mode 547
15.3 Clock Source Selection for Counter0 and Counter1 548
15.4 DCC Control Registers 549
15.4.1 DCC Global Control Register (DCCGCTRL) 550
15.4.2 DCC Revision Id Register (DCCREV) 551
15.4.3 DCC Counter0 Seed Register (DCCCNT0SEED) 551
15.4.4 DCC Valid0 Seed Register (DCCVALID0SEED) 552
15.4.5 DCC Counter1 Seed Register (DCCCNT1SEED) 552
15.4.6 DCC Status Register (DCCSTAT) 553
15.4.7 DCC Counter0 Value Register (DCCCNT0) 554
15.4.8 DCC Valid0 Value Register (DCCVALID0) 555
15.4.9 DCC Counter1 Value Register (DCCCNT1) 555
15.4.10 DCC Counter1 Clock Source Selection Register (DCCCNT1CLKSRC) 556
15.4.11 DCC Counter0 Clock Source Selection Register (DCCCNT0CLKSRC) 557

16.1 Overview 559
16.1.1 Feature List 559
16.1.2 Block Diagram 559
16.2 Module Operation 561
16.2.1 Reset Behavior 561
16.2.2 $\overline{\text{ERROR}}$ Pin Timing 562
16.2.3 Forcing an Error Condition 563
16.3 Recommended Programming Procedure 564
16.4 ESM Control Registers 565
16.4.1 ESM Enable $\overline{\text{ERROR}}$ Pin Action/Response Register 1 (ESMEEPAPR1) 566
16.4.2 ESM Disable $\overline{\text{ERROR}}$ Pin Action/Response Register 1 (ESMDEPAPR1) 566
16.4.3 ESM Interrupt Enable Set/Status Register 1 (ESMIESR1) 567
16.4.4 ESM Interrupt Enable Clear/Status Register 1 (ESMIECR1) 567
16.4.5 ESM Interrupt Level Set/Status Register 1 (ESMILSR1) 568
16.4.6 ESM Interrupt Level Clear/Status Register 1 (ESMILCR1) 568
16.4.7 ESM Status Register 1 (ESMSR1) 569
16.4.8 ESM Status Register 2 (ESMSR2) 569
16.4.9 ESM Status Register 3 (ESMSR3) 570
16.4.10 ESM $\overline{\text{ERROR}}$ Pin Status Register (ESMEPSR) 570
16.4.11 ESM Interrupt Offset High Register (ESMIOFFHR) 571
16.4.12 ESM Interrupt Offset Low Register (ESMIOFFLR) 572
16.4.13 ESM Low-Time Counter Register (ESMLTCR) 573
16.4.14 ESM Low-Time Counter Preload Register (ESMLTCPR) 573
16.4.15 ESM Error Key Register (ESMEKR) 574
16.4.16 ESM Status Shadow Register 2 (ESMSSR2) 574
16.4.17 ESM Influence $\overline{\text{ERROR}}$ Pin Set/Status Register 4 (ESMIEPSR4) 575
16.4.18 ESM Influence $\overline{\text{ERROR}}$ Pin Clear/Status Register 4 (ESMIEPCR4) 575
16.4.19 ESM Interrupt Enable Set/Status Register 4 (ESMIESR4) 576
16.4.20 ESM Interrupt Enable Clear/Status Register 4 (ESMIECR4) 576
16.4.21 ESM Interrupt Level Set/Status Register 4 (ESMILSR4) 577
16.4.22 ESM Interrupt Level Clear/Status Register 4 (ESMILCR4) 577
16.4.23 ESM Status Register 4 (ESMSR4) 578
16.4.24 ESM Influence $\overline{\text{ERROR}}$ Pin Set/Status Register 7 (ESMIEPSR7) 579
16.4.25 ESM Influence $\overline{\text{ERROR}}$ Pin Clear/Status Register 7 (ESMIEPCR7) 579
16.4.26 ESM Interrupt Enable Set/Status Register 7 (ESMIESR7) 580
16.4.27 ESM Interrupt Enable Clear/Status Register 7 (ESMIECR7) 580
16.4.28 ESM Interrupt Level Set/Status Register 7 (ESMILSR7) 581
16.4.29 ESM Interrupt Level Clear/Status Register 7 (ESMILCR7) 581
16.4.30 ESM Status Register 7 (ESMSR7) 582

17 Real-Time Interrupt (RTI) Module 583

17.1 Overview 584
17.1.1 Features 584
17.1.2 Industry Standard Compliance Statement 584
17.2 Module Operation 585
17.2.1 Counter Operation 585
17.2.2 Interrupt/DMA Requests 587
17.2.3 RTI Clocking 588
17.2.4 Synchronizing Timer Events to Network Time (NTU) 588
17.2.5 Digital Watchdog (DWD) 591
17.2.6 Low Power Modes 594
17.2.7 Halting Debug Mode Behaviour 594
17.3 RTI Control Registers 595
17.3.1 RTI Global Control Register (RTIGCTRL) 596

Copyright © 2018, Texas Instruments Incorporated

17.3.2 RTI Timebase Control Register (RTITBCTRL) 597
17.3.3 RTI Capture Control Register (RTICAPCTRL) 598
17.3.4 RTI Compare Control Register (RTICOMPCTRL) 599
17.3.5 RTI Free Running Counter 0 Register (RTIFRC0) 600
17.3.6 RTI Up Counter 0 Register (RTIUC0) 600
17.3.7 RTI Compare Up Counter 0 Register (RTICPUC0) 601
17.3.8 RTI Capture Free Running Counter 0 Register (RTICAFRC0) 601
17.3.9 RTI Capture Up Counter 0 Register (RTICAUC0) 602
17.3.10 RTI Free Running Counter 1 Register (RTIFRC1) 602
17.3.11 RTI Up Counter 1 Register (RTIUC1) 603
17.3.12 RTI Compare Up Counter 1 Register (RTICPUC1) 604
17.3.13 RTI Capture Free Running Counter 1 Register (RTICAFRC1) 605
17.3.14 RTI Capture Up Counter 1 Register (RTICAUC1) 605
17.3.15 RTI Compare 0 Register (RTICOMP0) 606
17.3.16 RTI Update Compare 0 Register (RTIUDCP0) 606
17.3.17 RTI Compare 1 Register (RTICOMP1) 607
17.3.18 RTI Update Compare 1 Register (RTIUDCP1) 607
17.3.19 RTI Compare 2 Register (RTICOMP2) 608
17.3.20 RTI Update Compare 2 Register (RTIUDCP2) 608
17.3.21 RTI Compare 3 Register (RTICOMP3) 609
17.3.22 RTI Update Compare 3 Register (RTIUDCP3) 609
17.3.23 RTI Timebase Low Compare Register (RTITBLCOMP) 610
17.3.24 RTI Timebase High Compare Register (RTITBHCOMP) 610
17.3.25 RTI Set Interrupt Enable Register (RTISETINTENA) 611
17.3.26 RTI Clear Interrupt Enable Register (RTICLEARINTENA) 613
17.3.27 RTI Interrupt Flag Register (RTIINTFLAG) 615
17.3.28 Digital Watchdog Control Register (RTIDWDCTRL) 616
17.3.29 Digital Watchdog Preload Register (RTIDWDPRLD) 617
17.3.30 Watchdog Status Register (RTIWDSTATUS) 618
17.3.31 RTI Watchdog Key Register (RTIWDKEY) 619
17.3.32 RTI Digital Watchdog Down Counter (RTIDWDCNTR) 620
17.3.33 Digital Windowed Watchdog Reaction Control (RTIWWDRXNCTRL) 620
17.3.34 Digital Windowed Watchdog Window Size Control (RTIWWDSIZECTRL) 621
17.3.35 RTI Compare Interrupt Clear Enable Register (RTIINTCLRENABLE) 622
17.3.36 RTI Compare 0 Clear Register (RTICMP0CLR) 623
17.3.37 RTI Compare 1 Clear Register (RTICMP1CLR) 623
17.3.38 RTI Compare 2 Clear Register (RTICMP2CLR) 624
17.3.39 RTI Compare 3 Clear Register (RTICMP3CLR) 624

18 Cyclic Redundancy Check (CRC) Controller Module 625

18.1 Overview 626
18.1.1 Features 626
18.1.2 Block Diagram 626
18.2 Module Operation 628
18.2.1 General Operation 628
18.2.2 CRC Modes of Operation 628
18.2.3 PSA Signature Register 629
18.2.4 PSA Sector Signature Register 630
18.2.5 CRC Value Register 631
18.2.6 Raw Data Register 631
18.2.7 Example DMA Controller Setup 631
18.2.8 Pattern Count Register 633
18.2.9 Sector Count Register/Current Sector Register 633
18.2.10 Interrupt 634

18.2.11 Power Down Mode 637
18.2.12 Emulation 637
18.2.13 Peripheral Bus Interface 638
18.3 Example 638
18.3.1 Example: Auto Mode Using Time Based Event Triggering 638
18.3.2 Example: Auto Mode Without Using Time Based Triggering 639
18.3.3 Example: Semi-CPU Mode 640
18.3.4 Example: Full-CPU Mode 640
18.4 CRC Control Registers 641
18.4.1 CRC Global Control Register 0 (CRC_CTRL0) 642
18.4.2 CRC Global Control Register (CRC_CTRL1) 642
18.4.3 CRC Global Control Register 2 (CRC_CTRL2) 643
18.4.4 CRC Interrupt Enable Set Register (CRC_INTS) 644
18.4.5 CRC Interrupt Enable Reset Register (CRC_INTR) 646
18.4.6 CRC Interrupt Status Register (CRC_STATUS) 648
18.4.7 CRC Interrupt Offset (CRC_INT_OFFSET_REG) 650
18.4.8 CRC Busy Register (CRC_BUSY) 651
18.4.9 CRC Pattern Counter Preload Register 1 (CRC_PCOUNT_REG1) 651
18.4.10 CRC Sector Counter Preload Register 1 (CRC_SCOUNT_REG1) 652
18.4.11 CRC Current Sector Register 1 (CRC_CURSEC_REG1) 652
18.4.12 CRC Channel 1 Watchdog Timeout Preload Register A (CRC_WDTOPLD1) 653
18.4.13 CRC Channel 1 Block Complete Timeout Preload Register B (CRC_BCTOPLD1) 653
18.4.14 Channel 1 PSA Signature Low Register (PSA_SIGREGL1) 654
18.4.15 Channel 1 PSA Signature High Register (PSA_SIGREGH1) 654
18.4.16 Channel 1 CRC Value Low Register (CRC_REGL1) 654
18.4.17 Channel 1 CRC Value High Register (CRC_REGH1) 655
18.4.18 Channel 1 PSA Sector Signature Low Register (PSA_SECSIGREGL1) 655
18.4.19 Channel 1 PSA Sector Signature High Register (PSA_SECSIGREGH1) 655
18.4.20 Channel 1 Raw Data Low Register (RAW_DATAREGL1) 656
18.4.21 Channel 1 Raw Data High Register (RAW_DATAREGH1) 656
18.4.22 CRC Pattern Counter Preload Register 2 (CRC_PCOUNT_REG2) 656
18.4.23 CRC Sector Counter Preload Register 2 (CRC_SCOUNT_REG2) 657
18.4.24 CRC Current Sector Register 2 (CRC_CURSEC_REG2) 657
18.4.25 CRC Channel 2 Watchdog Timeout Preload Register A (CRC_WDTOPLD2) 658
18.4.26 CRC Channel 2 Block Complete Timeout Preload Register B (CRC_BCTOPLD2) 658
18.4.27 Channel 2 PSA Signature Low Register (PSA_SIGREGL2) 659
18.4.28 Channel 2 PSA Signature High Register (PSA_SIGREGH2) 659
18.4.29 Channel 2 CRC Value Low Register (CRC_REGL2) 659
18.4.30 Channel 2 CRC Value High Register (CRC_REGH2) 660
18.4.31 Channel 2 PSA Sector Signature Low Register (PSA_SECSIGREGL2) 660
18.4.32 Channel 2 PSA Sector Signature High Register (PSA_SECSIGREGH2) 660
18.4.33 Channel 2 Raw Data Low Register (RAW_DATAREGL2) 661
18.4.34 Channel 2 Raw Data High Register (RAW_DATAREGH2) 661
19 Vectored Interrupt Manager (VIM) Module 662
19.1 Overview 663
19.2 Dual VIM for Safety 664
19.3 Device Level Interrupt Management 665
19.3.1 Interrupt Generation at the Peripheral 665
19.3.2 Interrupt Handling at the CPU 666
19.3.3 Software Interrupt Handling Options 667
19.4 Interrupt Handling Inside VIM 668
19.4.1 VIM Interrupt Channel Mapping 669

19.5 Interrupt Vector Table (VIM RAM) 672
19.5.1 Interrupt Vector Table Operation 672
19.5.2 VIM ECC Syndrome 673
19.5.3 Interrupt Vector Table Initialization 674
19.5.4 Interrupt Vector Table ECC Testing 674
19.6 VIM Wakeup Interrupt 676
19.7 Capture Event Sources 677
19.8 Examples 677
19.8.1 Examples - Configure CPU To Receive Interrupts 677
19.8.2 Examples - Register Vector Interrupt and Index Interrupt Handling 678
19.9 VIM Control Registers 680
19.9.1 Interrupt Vector Table ECC Status Register (ECCSTAT) 681
19.9.2 Interrupt Vector Table ECC Control Register (ECCCTL) 682
19.9.3 Uncorrectable Error Address Register (UERRADDR) 683
19.9.4 Fallback Vector Address Register (FBVECADDR) 683
19.9.5 Single-Bit Error Address Register (SBERRADDR) 684
19.9.6 VIM Offset Vector Registers 684
19.9.7 IRQ Index Offset Vector Register (IRQINDEX) 685
19.9.8 FIQ Index Offset Vector Registers (FIQINDEX) 685
19.9.9 FIQ/IRQ Program Control Registers (FIRQPR[0:3]) 686
19.9.10 Pending Interrupt Read Location Registers (INTREQ[0:3]) 687
19.9.11 Interrupt Enable Set Registers (REQENASET[0:3]) 688
19.9.12 Interrupt Enable Clear Registers (REQENACLR[0:3]) 689
19.9.13 Wake-Up Enable Set Registers (WAKEENASET[0:3]) 690
19.9.14 Wake-Up Enable Clear Registers (WAKEENACLR[0:3]) 691
19.9.15 IRQ Interrupt Vector Register (IRQVECREG) 692
19.9.16 FIQ Interrupt Vector Register (FIQVECREG) 692
19.9.17 Capture Event Register (CAPEVT) 693
19.9.18 VIM Interrupt Control Registers (CHANCTRL[0:31]) 694

20 Direct Memory Access Controller (DMA) Module 696

20.1 Overview 697
20.1.1 Main Features 697
20.1.2 System Resources Mapping 699
20.2 Module Operation 699
20.2.1 Memory Space 700
20.2.2 DMA Data Access 700
20.2.3 Addressing Modes 701
20.2.4 DMA Channel Control Packets 701
20.2.5 Priority Queue 705
20.2.6 Data Packing and Unpacking 707
20.2.7 DMA Request 710
20.2.8 Auto-Initiation 712
20.2.9 Interrupts 712
20.2.10 Debugging 714
20.2.11 Power Management 714
20.2.12 FIFO Buffer 715
20.2.13 Channel Chaining 716
20.2.14 Request Polarity 716
20.2.15 Memory Protection 717
20.2.16 ECC Checking 718
20.2.17 ECC Testing 719
20.2.18 Initializing RAM with ECC 719
20.2.19 Transaction Errors 720

20.3 Control Registers and Control Packets 721
20.3.1 Global Configuration Registers 724
20.3.2 Channel Configuration 788
21 External Memory Interface (EMIF) 793
21.1 Introduction 794
21.1.1 Purpose of the Peripheral 794
21.1.2 Features 794
21.1.3 Functional Block Diagram 795
21.2 EMIF Module Architecture 796
21.2.1 EMIF Clock Control 796
21.2.2 EMIF Requests 796
21.2.3 EMIF Signal Descriptions 796
21.2.4 EMIF Signal Multiplexing Control 797
21.2.5 SDRAM Controller and Interface 798
21.2.6 Asynchronous Controller and Interface 810
21.2.7 Data Bus Parking 822
21.2.8 Reset and Initialization Considerations 823
21.2.9 Interrupt Support 823
21.2.10 DMA Event Support 824
21.2.11 EMIF Signal Multiplexing 824
21.2.12 Memory Map 824
21.2.13 Priority and Arbitration 825
21.2.14 System Considerations 826
21.2.15 Power Management 827
21.2.16 Emulation Considerations 827
21.3 EMIF Registers 828
21.3.1 Module ID Register (MIDR) 828
21.3.2 Asynchronous Wait Cycle Configuration Register (AWCC) 829
21.3.3 SDRAM Configuration Register (SDCR) 830
21.3.4 SDRAM Refresh Control Register (SDRCR) 831
21.3.5 Asynchronous *n* Configuration Registers (CE2CFG-CE5CFG) 832
21.3.6 SDRAM Timing Register (SDTIMR) 833
21.3.7 SDRAM Self Refresh Exit Timing Register (SDSRETR) 834
21.3.8 EMIF Interrupt Raw Register (INTRAW) 835
21.3.9 EMIF Interrupt Masked Register (INTMSK) 836
21.3.10 EMIF Interrupt Mask Set Register (INTMSKSET) 837
21.3.11 EMIF Interrupt Mask Clear Register (INTMSKCLR) 838
21.3.12 Page Mode Control Register (PMCR) 839
21.4 Example Configuration 840
21.4.1 Hardware Interface 840
21.4.2 Software Configuration 840
22 Analog To Digital Converter (ADC) Module 848
22.1 Overview 849
22.1.1 Introduction 851
22.2 Basic Operation 853
22.2.1 Basic Features and Usage of the ADC 853
22.2.2 Advanced Conversion Group Configuration Options 860
22.2.3 ADC Module Basic Interrupts 868
22.2.4 ADC Module DMA Requests 869
22.2.5 ADC Magnitude Threshold Interrupts 870
22.2.6 ADC Special Modes 871
22.2.7 ADC Results' RAM Special Features 878
22.2.8 ADEVT Pin General Purpose I/O Functionality 879

22.3 ADC Registers 881
22.3.1 ADC Reset Control Register (ADRSTCR) 883
22.3.2 ADC Operating Mode Control Register (ADOPMODECR) 883
22.3.3 ADC Clock Control Register (ADCLOCKCR) 885
22.3.4 ADC Calibration Mode Control Register (ADCALCR) 885
22.3.5 ADC Event Group Operating Mode Control Register (ADEVMODECR) 887
22.3.6 ADC Group1 Operating Mode Control Register (ADG1MODECR) 890
22.3.7 ADC Group2 Operating Mode Control Register (ADG2MODECR) 893
22.3.8 ADC Event Group Trigger Source Select Register (ADEVSRC) 896
22.3.9 ADC Group1 Trigger Source Select Register (ADG1SRC) 897
22.3.10 ADC Group2 Trigger Source Select Register (ADG2SRC) 898
22.3.11 ADC Event Interrupt Enable Control Register (ADEVINTENA) 899
22.3.12 ADC Group1 Interrupt Enable Control Register (ADG1INTENA) 900
22.3.13 ADC Group2 Interrupt Enable Control Register (ADG2INTENA) 901
22.3.14 ADC Event Group Interrupt Flag Register (ADEVINTFLG) 902
22.3.15 ADC Group1 Interrupt Flag Register (ADG1INTFLG) 903
22.3.16 ADC Group2 Interrupt Flag Register (ADG2INTFLG) 904
22.3.17 ADC Event Group Threshold Interrupt Control Register (ADEVTHRINTCR) 905
22.3.18 ADC Group1 Threshold Interrupt Control Register (ADG1THRINTCR) 905
22.3.19 ADC Group2 Threshold Interrupt Control Register (ADG2THRINTCR) 906
22.3.20 ADC Event Group DMA Control Register (ADEVDMACR) 907
22.3.21 ADC Group1 DMA Control Register (ADG1DMACR) 909
22.3.22 ADC Group2 DMA Control Register (ADG2DMACR) 911
22.3.23 ADC Results Memory Configuration Register (ADBNDCR) 913
22.3.24 ADC Results Memory Size Configuration Register (ADBNDEND) 914
22.3.25 ADC Event Group Sampling Time Configuration Register (ADEVSAMP) 915
22.3.26 ADC Group1 Sampling Time Configuration Register (ADG1SAMP) 915
22.3.27 ADC Group2 Sampling Time Configuration Register (ADG2SAMP) 916
22.3.28 ADC Event Group Status Register (ADEVSR) 917
22.3.29 ADC Group1 Status Register (ADG1SR) 918
22.3.30 ADC Group2 Status Register (ADG2SR) 919
22.3.31 ADC Event Group Channel Select Register (ADEVSEL) 920
22.3.32 ADC Group1 Channel Select Register (ADG1SEL) 921
22.3.33 ADC Group2 Channel Select Register (ADG2SEL) 922
22.3.34 ADC Calibration and Error Offset Correction Register (ADCALR) 923
22.3.35 ADC State Machine Status Register (ADSMSTATE) 923
22.3.36 ADC Channel Last Conversion Value Register (ADLASTCONV) 924
22.3.37 ADC Event Group Results' FIFO Register (ADEVBUFFER) 925
22.3.38 ADC Group1 Results FIFO Register (ADG1BUFFER) 926
22.3.39 ADC Group2 Results FIFO Register (ADG2BUFFER) 927
22.3.40 ADC Event Group Results Emulation FIFO Register (ADEVEMUBUFFER) 928
22.3.41 ADC Group1 Results Emulation FIFO Register (ADG1EMUBUFFER) 929
22.3.42 ADC Group2 Results Emulation FIFO Register (ADG2EMUBUFFER) 930
22.3.43 ADC ADEVT Pin Direction Control Register (ADEVTDIR) 931
22.3.44 ADC ADEVT Pin Output Value Control Register (ADEVTOUT) 932
22.3.45 ADC ADEVT Pin Input Value Register (ADEVTIN) 932
22.3.46 ADC ADEVT Pin Set Register (ADEVTSET) 933
22.3.47 ADC ADEVT Pin Clear Register (ADEVTCLR) 933
22.3.48 ADC ADEVT Pin Open Drain Enable Register (ADEVTPDR) 934
22.3.49 ADC ADEVT Pin Pull Control Disable Register (ADEVTPDIS) 934
22.3.50 ADC ADEVT Pin Pull Control Select Register (ADEVTPSEL) 935

22.3.55 ADC Magnitude Compare Interruptx Mask Register (ADMAGINTxMASK) 940
22.3.56 ADC Magnitude Compare Interrupt Enable Set Register (ADMAGINTENASET) 941
22.3.57 ADC Magnitude Compare Interrupt Enable Clear Register (ADMAGINTENACLR) 941
22.3.58 ADC Magnitude Compare Interrupt Flag Register (ADMAGINTFLG) 942
22.3.59 ADC Magnitude Compare Interrupt Offset Register (ADMAGINTOFF) 942
22.3.60 ADC Event Group FIFO Reset Control Register (ADEVFIFORESETCR) 943
22.3.61 ADC Group1 FIFO Reset Control Register (ADG1FIFORESETCR) 943
22.3.62 ADC Group2 FIFO Reset Control Register (ADG2FIFORESETCR) 944
22.3.63 ADC Event Group RAM Write Address Register (ADEVRAMWRADDR) 944
22.3.64 ADC Group1 RAM Write Address Register (ADG1RAMWRADDR) 945
22.3.65 ADC Group2 RAM Write Address Register (ADG2RAMWRADDR) 945
22.3.66 ADC Parity Control Register (ADPARCR) 946
22.3.67 ADC Parity Error Address Register (ADPARADDR) 947
22.3.68 ADC Power-Up Delay Control Register (ADPWRUPDLYCTRL) 947
22.3.69 ADC Event Group Channel Selection Mode Control Register (ADEVCHNSELMODECTRL) 948
22.3.70 ADC Group1 Channel Selection Mode Control Register (ADG1CHNSELMODECTRL) 948
22.3.71 ADC Group2 Channel Selection Mode Control Register (ADG2CHNSELMODECTRL) 949
22.3.72 ADC Event Group Current Count Register (ADEVCURRCOUNT) 950
22.3.73 ADC Event Group Maximum Count Register (ADEVMAXCOUNT) 950
22.3.74 ADC Group1 Current Count Register (ADG1CURRCOUNT) 951
22.3.75 ADC Group1 Maximum Count Register (ADG1MAXCOUNT) 951
22.3.76 ADC Group2 Current Count Register (ADG2CURRCOUNT) 952
22.3.77 ADC Group2 Maximum Count Register (ADG2MAXCOUNT) 952

23 High-End Timer (N2HET) Module 953

23.1 Overview 954
23.1.1 Features 954
23.1.2 Major Advantages 954
23.1.3 Block Diagram 955
23.1.4 Timer Module Structure and Execution 956
23.1.5 Performance 957
23.1.6 N2HET Compared to NHET 957
23.1.7 NHET and N2HET Compared to HET 957
23.1.8 Instructions Features 958
23.1.9 Program Usage 958
23.2 N2HET Functional Description 958
23.2.1 Specialized Timer Micromachine 958
23.2.2 N2HET RAM Organization 963
23.2.3 Time Base 966
23.2.4 Host Interface 969
23.2.5 I/O Control 970
23.2.6 Suppression Filters 986
23.2.7 Interrupts and Exceptions 987
23.2.8 Hardware Priority Scheme 988
23.2.9 N2HET Requests to DMA and HTU 990
23.3 Angle Functions 990
23.3.1 Software Angle Generator 990
23.3.2 Hardware Angle Generator (HWAG) 995
23.4 N2HET Control Registers 1017
23.4.1 Global Configuration Register (HETGCR) 1018
23.4.2 Prescale Factor Register (HETPFR) 1020
23.4.3 N2HET Current Address Register (HETADDR) 1021

Copyright © 2018, Texas Instruments Incorporated

23.4.4 Offset Index Priority Level 1 Register (HETOFF1) 1021
23.4.5 Offset Index Priority Level 2 Register (HETOFF2) 1022
23.4.6 Interrupt Enable Set Register (HETINTENAS) 1023
23.4.7 Interrupt Enable Clear Register (HETINTENAC) 1023
23.4.8 Exception Control Register 1 (HETEXC1) 1024
23.4.9 Exception Control Register 2 (HETEXC2) 1025
23.4.10 Interrupt Priority Register (HETPRY) 1026
23.4.11 Interrupt Flag Register (HETFLG) 1026
23.4.12 AND Share Control Register (HETAND) 1027
23.4.13 HR Share Control Register (HETHRSH) 1028
23.4.14 XOR Share Control Register (HETXOR) 1029
23.4.15 Request Enable Set Register (HETREQENS) 1030
23.4.16 Request Enable Clear Register (HETREQENC) 1030
23.4.17 Request Destination Select Register (HETREQDS) 1031
23.4.18 NHET Direction Register (HETDIR) 1032
23.4.19 N2HET Data Input Register (HETDIN) 1033
23.4.20 N2HET Data Output Register (HETDOUT) 1033
23.4.21 NHET Data Set Register (HETDSET) 1034
23.4.22 N2HET Data Clear Register (HETDCLR) 1034
23.4.23 N2HET Open Drain Register (HETPDR) 1035
23.4.24 N2HET Pull Disable Register (HETPULDIS) 1035
23.4.25 N2HET Pull Select Register (HETPSL) 1036
23.4.26 Parity Control Register (HETPCR) 1037
23.4.27 Parity Address Register (HETPAR) 1038
23.4.28 Parity Pin Register (HETPPR) 1039
23.4.29 Suppression Filter Preload Register (HETSFPRLD) 1040
23.4.30 Suppression Filter Enable Register (HETSFENA) 1040
23.4.31 Loop Back Pair Select Register (HETLBPSEL) 1041
23.4.32 Loop Back Pair Direction Register (HETLBPDIR) 1042
23.4.33 N2HET Pin Disable Register (HETPINDIS) 1043
23.5 HWAG Registers 1044
23.5.1 HWAG Pin Select Register (HWAPINSEL) 1045
23.5.2 HWAG Global Control Register 0 (HWAGCR0) 1046
23.5.3 HWAG Global Control Register 1 (HWAGCR1) 1046
23.5.4 HWAG Global Control Register 2 (HWAGCR2) 1047
23.5.5 HWAG Interrupt Enable Set Register (HWAENASET) 1048
23.5.6 HWAG Interrupt Enable Clear Register (HWAENACLR) 1049
23.5.7 HWAG Interrupt Level Set Register (HWALVLSET) 1050
23.5.8 HWAG Interrupt Level Clear Register (HWALVLCLR) 1050
23.5.9 HWAG Interrupt Flag Register (HWAFLG) 1051
23.5.10 HWAG Interrupt Offset Register 0 (HWAOFF0) 1052
23.5.11 HWAG Interrupt Offset Register 1 (HWAOFF1) 1053
23.5.12 HWAG Angle Value Register (HWAACNT) 1054
23.5.13 HWAG Previous Tooth Period Value Register (HWAPCNT1) 1055
23.5.14 HWAG Current Tooth Period Value Register (HWAPCNT) 1055
23.5.15 HWAG Step Width Register (HWASTWD) 1056
23.5.16 HWAG Teeth Number Register (HWATHNB) 1057
23.5.17 HWAG Current Teeth Number Register (HWATHVL) 1057
23.5.18 HWAG Filter Register (HWAFIL) 1058
23.5.19 HWAG Filter Register 2 (HWAFIL2) 1058
23.5.20 HWAG Angle Increment Register (HWAANGI) 1059
23.6 Instruction Set 1060

23.6.3 Instruction Description 1065

24 High-End Timer Transfer Unit (HTU) Module 1131

24.1 Overview 1132
24.1.1 Features 1132
24.2 Module Operation 1133
24.2.1 Data Transfers between Main RAM and N2HET RAM 1135
24.2.2 Arbitration of HTU Elements and Frames 1139
24.2.3 Conditions for Frame Transfer Interruption 1140
24.2.4 HTU Overload and Request Lost Detection 1140
24.2.5 Memory Protection 1143
24.2.6 Control Packet RAM Parity Checking 1143
24.3 Use Cases 1145
24.3.1 Example: Single Element Transfer with One Trigger Request 1145
24.3.2 Example: Multiple Element Transfer with One Trigger Request 1145
24.3.3 Example: 64-Bit-Transfer of Control Field and Data Fields 1147
24.4 HTU Control Registers 1148
24.4.1 Global Control Register (HTU GC) 1149
24.4.2 Control Packet Enable Register (HTU CPENA) 1150
24.4.3 Control Packet (CP) Busy Register 0 (HTU BUSY0) 1151
24.4.4 Control Packet (CP) Busy Register 1 (HTU BUSY1) 1152
24.4.5 Control Packet (CP) Busy Register 2 (HTU BUSY2) 1152
24.4.6 Control Packet (CP) Busy Register 3 (HTU BUSY3) 1153
24.4.7 Active Control Packet and Error Register (HTU ACPE) 1153
24.4.8 Request Lost and Bus Error Control Register (HTU RLBECTRL) 1155
24.4.9 Buffer Full Interrupt Enable Set Register (HTU BFINTS) 1156
24.4.10 Buffer Full Interrupt Enable Clear Register (HTU BFINTC) 1156
24.4.11 Interrupt Mapping Register (HTU INTMAP) 1157
24.4.12 Interrupt Offset Register 0 (HTU INTOFF0) 1158
24.4.13 Interrupt Offset Register 1 (HTU INTOFF1) 1159
24.4.14 Buffer Initialization Mode Register (HTU BIM) 1160
24.4.15 Request Lost Flag Register (HTU RLOSTFL) 1162
24.4.16 Buffer Full Interrupt Flag Register (HTU BFINTFL) 1162
24.4.17 BER Interrupt Flag Register (HTU BERINTFL) 1163
24.4.18 Memory Protection 1 Start Address Register (HTU MP1S) 1164
24.4.19 Memory Protection 1 End Address Register (HTU MP1E) 1164
24.4.20 Debug Control Register (HTU DCTRL) 1165
24.4.21 Watch Point Register (HTU WPR) 1166
24.4.22 Watch Mask Register (HTU WMR) 1166
24.4.23 Module Identification Register (HTU ID) 1167
24.4.24 Parity Control Register (HTU PCR) 1168
24.4.25 Parity Address Register (HTU PAR) 1169
24.4.26 Memory Protection Control and Status Register (HTU MPCS) 1170
24.4.27 Memory Protection Start Address Register 0 (HTU MP0S) 1173
24.4.28 Memory Protection End Address Register (HTU MP0E) 1173
24.5 Double Control Packet Configuration Memory 1174
24.5.1 Initial Full Address A Register (HTU IFADDRA) 1175
24.5.2 Initial Full Address B Register (HTU IFADDRB) 1175
24.5.3 Initial N2HET Address and Control Register (HTU IHADDRCT) 1176
24.5.4 Initial Transfer Count Register (HTU ITCOUNT) 1177
24.5.5 Current Full Address A Register (HTU CFADDRA) 1178
24.5.6 Current Full Address B Register (HTU CFADDRB) 1179
24.5.7 Current Frame Count Register (HTU CFCOUNT) 1180

24.6 Examples 1181
24.6.1 Application Examples for Setting the Transfer Modes of CP A and B of a DCP 1181
24.6.2 Software Example Sequence Assuming Circular Mode for Both CP A and B 1181
24.6.3 Example of an Interrupt Dispatch Flow for a Request Lost Interrupt 1182
25 General-Purpose Input/Output (GIO) Module 1183
25.1 Overview 1184
25.2 Quick Start Guide 1185
25.3 Functional Description of GIO Module 1187
25.3.1 I/O Functions 1187
25.3.2 Interrupt Function 1188
25.3.3 GIO Block Diagram 1188
25.4 Device Modes of Operation 1190
25.4.1 Emulation Mode 1190
25.4.2 Power-Down Mode (Low-Power Mode) 1190
25.5 GIO Control Registers 1191
25.5.1 GIO Global Control Register (GIOGCR0) 1192
25.5.2 GIO Interrupt Detect Register (GIOINTDET) 1193
25.5.3 GIO Interrupt Polarity Register (GIOPOL) 1194
25.5.4 GIO Interrupt Enable Registers (GIOENASET and GIOENACLR) 1195
25.5.5 GIO Interrupt Priority Registers (GIOLVLSET and GIOLVLCLR) 1197
25.5.6 GIO Interrupt Flag Register (GIOFLG) 1200
25.5.7 GIO Offset Register 1 (GIOOFF1) 1201
25.5.8 GIO Offset B Register (GIOOFF2) 1202
25.5.9 GIO Emulation A Register (GIOEMU1) 1203
25.5.10 GIO Emulation B Register (GIOEMU2) 1204
25.5.11 GIO Data Direction Registers (GIODIR[A-B]) 1205
25.5.12 GIO Data Input Registers (GIODIN[A-B]) 1205
25.5.13 GIO Data Output Registers (GIODOUT[A-B]) 1206
25.5.14 GIO Data Set Registers (GIODSET[A-B]) 1206
25.5.15 GIO Data Clear Registers (GIODCLR[A-B]) 1207
25.5.16 GIO Open Drain Registers (GIOPDR[A-B]) 1207
25.5.17 GIO Pull Disable Registers (GIOPULDIS[A-B]) 1208
25.5.18 GIO Pull Select Registers (GIOPSL[A-B]) 1208
25.6 I/O Control Summary 1209
26 FlexRay Module 1210
26.1 Overview 1211
26.1.1 Feature List 1211
26.1.2 FlexRay Module Block Diagram 1211
26.1.3 FlexRay Module Blocks 1214
26.2 Module Operation 1215
26.2.1 Transfer Unit 1215
26.2.2 Communication Cycle 1226
26.2.3 Communication Modes 1227
26.2.4 Clock Synchronization 1228
26.2.5 Error Handling 1229
26.2.6 Communication Controller States 1231
26.2.7 Network Management 1243
26.2.8 Filtering and Masking 1243
26.2.9 Transmit Process 1246
26.2.10 Receive Process 1248
26.2.11 FIFO Function 1249
26.2.12 Message Handling 1250

26.2.15 Minimum Peripheral Clock Frequency 1274
26.2.16 Assignment of FlexRay Configuration Parameters 1275
26.2.17 Emulation/Debug Support 1276
26.3 FlexRay Module Registers 1277
26.3.1 Transfer Unit Registers 1277
26.3.2 Communication Controller Registers 1325
27 Controller Area Network (DCAN) Module 1417
27.1 Overview 1418
27.1.1 Features 1418
27.1.2 Functional Description 1418
27.2 CAN Blocks 1419
27.2.1 CAN Core 1419
27.2.2 Message RAM 1419
27.2.3 Message Handler 1419
27.2.4 Message RAM Interface 1420
27.2.5 Register and Message Object Access 1420
27.2.6 Dual Clock Source 1420
27.3 CAN Bit Timing 1421
27.3.1 Bit Time and Bit Rate 1421
27.3.2 DCAN Bit Timing Registers 1423
27.4 CAN Module Configuration 1425
27.4.1 DCAN RAM Initialization Through Hardware 1425
27.4.2 CAN Module Initialization 1425
27.5 Message RAM 1428
27.5.1 Structure of Message Objects 1428
27.5.2 Addressing Message Objects in RAM 1430
27.5.3 Message RAM Representation in Debug/Suspend Mode 1431
27.5.4 Message RAM Representation in Direct Access Mode 1431
27.5.5 ECC RAM 1432
27.6 Message Interface Register Sets 1433
27.6.1 Message Interface Register Sets 1 and 2 1433
27.6.2 Using Message Interface Register Sets 1 and 2 1434
27.6.3 Message Interface Register 3 1435
27.7 Message Object Configurations 1436
27.7.1 Configuration of a Transmit Object for Data Frames 1436
27.7.2 Configuration of a Transmit Object for Remote Frames 1436
27.7.3 Configuration of a Single Receive Object for Data Frames 1436
27.7.4 Configuration of a Single Receive Object for Remote Frames 1437
27.7.5 Configuration of a FIFO Buffer 1437
27.7.6 Reconfiguration of Message Objects for the Reception of Frames 1437
27.7.7 Reconfiguration of Message Objects for the Transmission of Frames 1437
27.8 Message Handling 1438
27.8.1 Message Handler Overview 1438
27.8.2 Receive/Transmit Priority 1438
27.8.3 Transmission of Messages in Event Driven CAN Communication 1439
27.8.4 Updating a Transmit Object 1439
27.8.5 Changing a Transmit Object 1439
27.8.6 Acceptance Filtering of Received Messages 1440
27.8.7 Reception of Data Frames 1440
27.8.8 Reception of Remote Frames 1440
27.8.9 Reading Received Messages 1440
27.8.10 Requesting New Data for a Receive Object 1441

27.8.11 Storing Received Messages in FIFO Buffers 1441
27.8.12 Reading from a FIFO Buffer 1441
27.9 CAN Message Transfer 1443
27.9.1 Automatic Retransmission 1443
27.9.2 Auto-Bus-On 1444
27.10 Interrupt Functionality 1444
27.10.1 Message Object Interrupts 1444
27.10.2 Status Change Interrupts 1445
27.10.3 Error Interrupts 1445
27.11 Global Power Down Mode 1446
27.11.1 Entering Global Power Down Mode 1446
27.11.2 Wakeup From Global Power Down Mode 1446
27.12 Local Power Down Mode 1447
27.12.1 Entering Local Power Down Mode 1447
27.12.2 Wakeup From Local Power Down 1447
27.13 GIO Support 1447
27.14 Test Modes 1449
27.14.1 Silent Mode 1449
27.14.2 Loop Back Mode 1450
27.14.3 External Loop Back Mode 1451
27.14.4 Loop Back Combined with Silent Mode 1452
27.14.5 Software Control of CAN_TX Pin 1452
27.15 SECDED Mechanism 1453
27.15.1 Behavior on Single-Bit Error 1453
27.15.2 Behavior on Double-Bit Error 1453
27.15.3 SECDED Testing 1453
27.16 Debug/Suspend Mode 1454
27.17 DCAN Control Registers 1454
27.17.1 CAN Control Register (DCAN CTL) 1456
27.17.2 Error and Status Register (DCAN ES) 1459
27.17.3 Error Counter Register (DCAN ERRC) 1461
27.17.4 Bit Timing Register (DCAN BTR) 1462
27.17.5 Interrupt Register (DCAN INT) 1463
27.17.6 Test Register (DCAN TEST) 1464
27.17.7 Parity Error Code Register (DCAN PERR) 1465
27.17.8 Core Release Register (DCAN REL) 1465
27.17.9 ECC Diagnostic Register (DCAN ECCDIAG) 1466
27.17.10 ECC Diagnostic Status Register (DCAN ECCDIAG STAT) 1466
27.17.11 ECC Control and Status Register (DCAN ECC CS) 1467
27.17.12 ECC Single-Bit Error Code Register (DCAN ECC SERR) 1468
27.17.13 Auto-Bus-On Time Register (DCAN ABOTR) 1469
27.17.14 Transmission Request X Register (DCAN TXRQ X) 1469
27.17.15 Transmission Request Registers (DCAN TXRQ12 to DCAN TXRQ78) 1470
27.17.16 New Data X Register (DCAN NWDAT X) 1471
27.17.17 New Data Registers (DCAN NWDAT12 to DCAN NWDAT78) 1472
27.17.18 Interrupt Pending X Register (DCAN INTPND X) 1473
27.17.19 Interrupt Pending Registers (DCAN INTPND12 to DCAN INTPND78) 1474
27.17.20 Message Valid X Register (DCAN MSGVAL X) 1475
27.17.21 Message Valid Registers (DCAN MSGVAL12 to DCAN MSGVAL78) 1476
27.17.22 Interrupt Multiplexer Registers (DCAN INTMUX12 to DCAN INTMUX78) 1477
27.17.23 IF1/IF2 Command Registers (DCAN IF1CMD, DCAN IF2CMD) 1478
27.17.24 IF1/IF2 Mask Registers (DCAN IF1MSK, DCAN IF2MSK) 1481

27.17.35 CAN RX IO Control Register (DCAN RIOC) 1495

28 Multi-Buffered Serial Peripheral Interface Module (MibSPI) with Parallel Pin Option (MibSPIP) . 1497

28.1 Overview 1498
28.1.1 Features 1498
28.1.2 Pin Configurations 1499
28.1.3 MibSPI /SPI Configurations 1500
28.2 Basic Operation 1500
28.2.1 SPI Mode 1500
28.2.2 MibSPI Mode 1502
28.2.3 DMA Requests 1503
28.2.4 Interrupts 1505
28.2.5 Physical Interface 1507
28.2.6 Advanced Module Configuration Options 1511
28.2.7 General-Purpose I/O 1529
28.2.8 Low-Power Mode 1529
28.2.9 Safety Features 1529
28.2.10 Test Features 1531
28.2.11 Module Configuration 1533
28.3 Control Registers 1535
28.3.1 SPI Global Control Register 0 (SPIGCR0) 1536
28.3.2 SPI Global Control Register 1 (SPIGCR1) 1537
28.3.3 SPI Interrupt Register (SPIINT0) 1538
28.3.4 SPI Interrupt Level Register (SPILVL) 1540
28.3.5 SPI Flag Register (SPIFLG) 1541
28.3.6 SPI Pin Control Register 0 (SPIPC0) 1544
28.3.7 SPI Pin Control Register 1 (SPIPC1) 1545
28.3.8 SPI Pin Control Register 2 (SPIPC2) 1547
28.3.9 SPI Pin Control Register 3 (SPIPC3) 1548
28.3.10 SPI Pin Control Register 4 (SPIPC4) 1549
28.3.11 SPI Pin Control Register 5 (SPIPC5) 1551
28.3.12 SPI Pin Control Register 6 (SPIPC6) 1552
28.3.13 SPI Pin Control Register 7 (SPIPC7) 1554
28.3.14 SPI Pin Control Register 8 (SPIPC8) 1555
28.3.15 SPI Transmit Data Register 0 (SPIDAT0) 1556
28.3.16 SPI Transmit Data Register 1 (SPIDAT1) 1557
28.3.17 SPI Receive Buffer Register (SPIBUF) 1560
28.3.18 SPI Emulation Register (SPIEMU) 1562
28.3.19 SPI Delay Register (SPIDELAY) 1562
28.3.20 SPI Default Chip Select Register (SPIDEF) 1565
28.3.21 SPI Data Format Registers (SPIFMT[3:0]) 1566
28.3.22 Interrupt Vector 0 (INTVECT0) 1568
28.3.23 Interrupt Vector 1 (INTVECT1) 1569
28.3.24 SPI Pin Control Register 9 (SPIPC9) 1571
28.3.25 Parallel/Modulo Mode Control Register (SPIPMCTRL) 1572

About This Manual

This Technical Reference Manual (TRM) details the integration, the environment, the functional description, and the programming models for each peripheral and subsystem in the device.

The TRM should not be considered a substitute for the data manual, rather a companion guide that should be used alongside the device-specific data manual to understand the details to program the device. The primary purpose of the TRM is to abstract the programming details of the device from the data manual. This allows the data manual to outline the high-level features of the device without unnecessary information about register descriptions or programming models.

Notational Conventions

This document uses the following conventions.

- Hexadecimal numbers may be shown with the suffix h or the prefix 0x. For example, the following number is 40 hexadecimal (decimal 64): 40h or 0x40.
- Registers in this document are shown in figures and described in tables.
  - Each register figure shows a rectangle divided into fields that represent the fields of the register. Each field is labeled with its bit name, its beginning and ending bit numbers above, and its read/write properties with default reset value below. A legend explains the notation used for the properties.
  - Reserved bits in a register figure can have one of multiple meanings:
    - Not implemented on the device
    - Reserved for future device expansion
    - Reserved for TI testing
    - Reserved configurations of the device that are not supported
  - Writing nondefault values to the Reserved bits could cause unexpected behavior and should be avoided.

Glossary

TI Glossary —This glossary lists and explains terms, acronyms, and definitions.

1.1 Designed for Safety Applications

The TMS570LC43x device architecture has been designed from the ground up to simplify development of functionally safe systems. The basic architectural concept is known as a safe island approach. Power, clock, reset, and basic processing function are protected to a high level of diagnostic coverage in hardware. Some of the key features of the safe island region are:

- Lockstep safety concept is also extended to the Vector Interrupt Module (VIM). Dual VIMs in lockstep that detect failures at the controller's boundary on a cycle by cycle basis. VIMs internal RAM that stores the vector addresses is also ECC protected.
- ECC diagnostic for the datapath on the Level 1 cache memories as well as ECC on the Level 2 SRAM and flash memories of the R5F core. The ECC controllers are located inside the CPU for each respective memory interface. This approach has two key advantages:
  - The interconnect between CPU and the memory is also covered by the diagnostic.
  - The ECC logic itself is checked on a cycle by cycle basis.
- Hardware BIST controllers that provide an extremely high level of diagnostic coverage for the lockstep CPUs and SRAMs in the system, while executing faster and consuming less memory than equivalent software-based self-test solutions.
- Hardware BIST diagnostic also for both the N2HET timer coprocessors.
- Interconnect between the masters and the level 2 memories contain built-in hardware safety diagnostic logic that monitors the integrity of traffics in each cycle
  - Continuous monitoring of transactions going in and out of the interconnect.
  - Parity diagnostic on the address and control paths between all masters and slaves
  - BIST mode for diagnostic coverage of the interconnect.
  - ECC generation and evaluation for transactions on the datapath generated for some of the bus masters.
- Onboard voltage and reset monitoring logic
- Onboard oscillator and PLL failure detection logic including a backup RC oscillator that can be utilized upon failure

The TMS570LC43x device architecture also includes many features to simplify diagnostics of remaining logic such as:

- Continuous parity or ECC diagnostics on all peripheral memories.
- Analog and digital loopback to test for shorts on I/O.
- HW self-test and diagnostics on the ADC module to check integrity of both analog inputs and the ADC core conversion function.
- A DMA driven hardware engine for the background calculation of CRC signatures during data transfers.
- A centralized error reporting function including a status output pin to enable external monitoring of the device status.

1.2 Family Description

The TMS570LC43x family of microcontrollers are cache-based architecture based on the ARM® Cortex®-R5F Floating Point CPU that offers an efficient 1.66 DMIPS/MHz performance and has configurations that can run up to 330 MHz providing up to 498 DMIPS. The device supports the big-endian [BE32] format.

The TMS570LC43x has up to 4MB integrated Flash and up to 512KB data RAM configurations with single bit error correction and double bit error detection. The flash memory on this device is a nonvolatile, electrically erasable and programmable memory implemented with a 64-bit-wide data bus interface. The flash operates on a 3.3V supply input (same level as I/O supply) for all read, program and erase operations. The SRAM operates with a system clock frequency of up to 150 MHz. The SRAM supports read/write accesses in byte, halfword, and word modes.

The TMS570LC43x device features peripherals for real-time control-based applications, including two Next Generation High End Timer (N2HET) timing coprocessors with up to 64 total IO terminals and two 12-bit A to D converters supporting up to 41 inputs.

The N2HET is an advanced intelligent timer that provides sophisticated timing functions for real-time applications. The timer is software-controlled, using a reduced instruction set, with a specialized timer micromachine and an attached I/O port. The N2HET can be used for pulse width modulated outputs, capture or compare inputs, or general-purpose I/O. It is especially well suited for applications requiring multiple sensor information and drive actuators with complex and accurate time pulses. A High End Timer Transfer Unit (HET-TU) can perform DMA type transactions to transfer N2HET data to or from main memory. A Memory Protection Unit (MPU) is built into the HET-TU.

The device has two 12-bit-resolution MibADCs with 41 total channels and 64 words of parity protected buffer RAM each. The MibADC channels can be converted individually or can be grouped by software for sequential conversion sequences. Sixteen channels are shared between the two MibADCs. There are three separate groupings. Each sequence can be converted once when triggered or configured for continuous conversion mode.

There are three on-die temperature sensors on this device. The temperature measurements of the three temperature sensors are routed to the MibADC for conversion into digital values. CPU can read out the digital values and compare with the calibrated temperature value stored in the device's OTP.

The device has multiple communication interfaces: Five MibSPIs, two LINs, two SCIs, four DCANs, two I^2C, one Ethernet, and one FlexRay controller. The MibSPI provides a convenient method of serial interaction for high-speed communications between similar shift-register type devices. Data stored in the MibSPI's buffer RAM are protected with ECC. The LIN supports the Local Interconnect standard 2.0 and can be used as a UART in full-duplex mode using the standard Non-Return-to-Zero (NRZ) format. The DCAN supports the CAN 2.0B protocol standard and uses a serial, multimaster communication protocol that efficiently supports distributed real-time control with robust communication rates of up to 1 megabit per second (Mbps). The DCAN is ideal for applications operating in noisy and harsh environments (for example, automotive and industrial fields) that require reliable serial communication or multiplexed wiring. Messages stored at the DCAN's RAM are protected with ECC. The FlexRay uses a dual channel serial, fixed time base multimaster communication protocol with communication rates of 10 megabits per second (Mbps) per channel. Messages stored at the FlexRay's RAM are ECC protected. A FlexRay Transfer Unit (FTU) enables autonomous transfers of FlexRay data to and from main CPU memory. Transfers are protected by a dedicated, built-in Memory Protection Unit (MPU). The Ethernet module supports MII and MDIO interfaces. Transfers are protected by a standalone Enhanced Memory Protection Unit (NMPU)

The I2C module is a multi-master communication module providing an interface between the microcontroller and an I2C compatible device via the I2C serial bus. The I2C supports both 100 Kbps and 400 Kbps speeds.

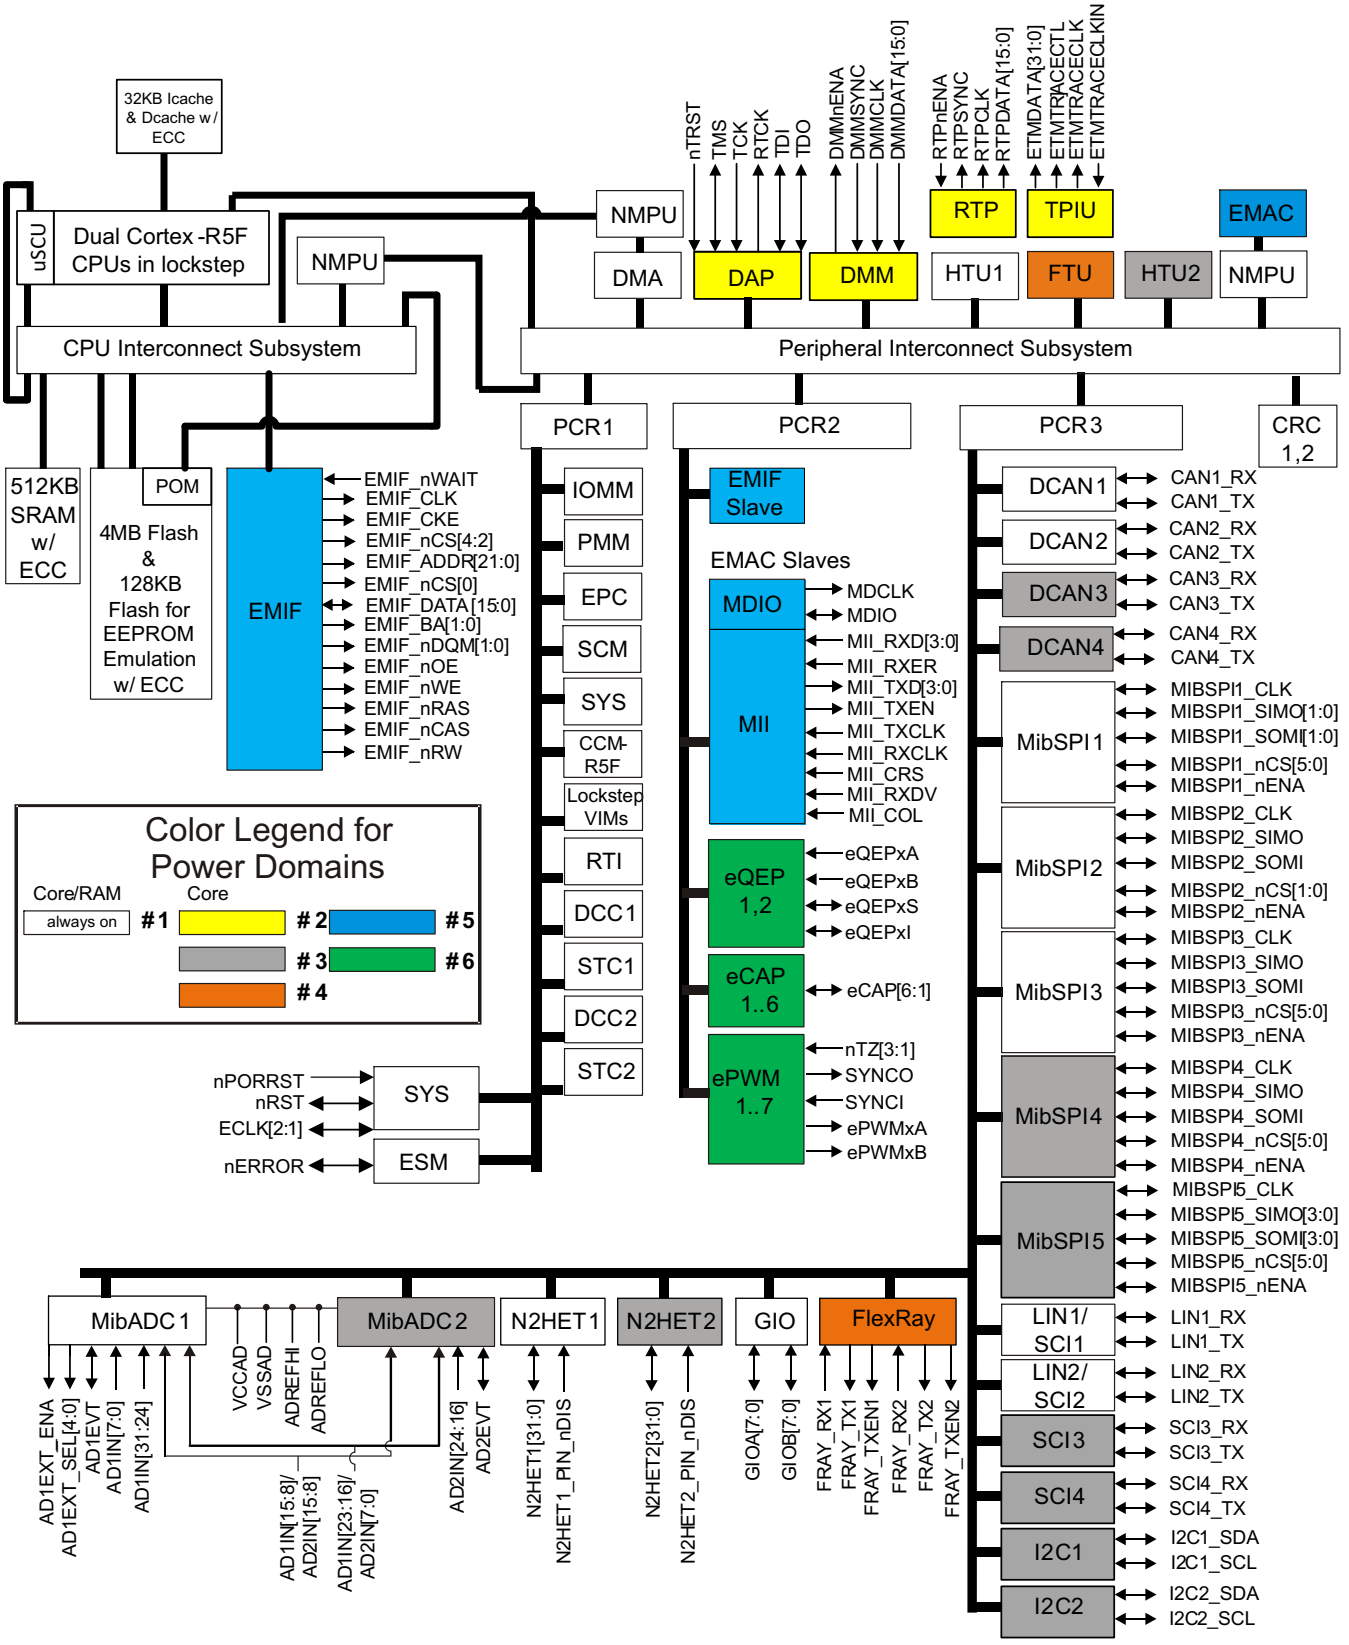
The frequency-modulated phase-locked loop (FMPLL) clock module is used to multiply the external frequency reference to a higher frequency for internal use. The FMPLL provides one of the seven possible clock source inputs to the global clock module (GCM). The GCM module manages the mapping between the available clock sources and the device clock domains.

The device also has two external clock prescaler (ECP) modules that when enabled, outputs a continuous external clock on the ECLK1 and ECLK2 terminals. The ECLK frequency is a user-programmable ratio of the peripheral interface clock (VCLK) frequency. This low frequency output can be monitored externally as an indicator of the device operating frequency.

Copyright © 2018, Texas Instruments Incorporated

The Direct Memory Access Controller (DMA) is capable of issuing multi-threaded transactions at the same time. It can support up to 48 DMA requests that can be mapped to any one of the 32 channels. 32 control packets implemented in RAM to store channel control information are ECC protected. A first level Memory Protection Unit (MPU) is built into the DMA and a second level standalone Enhanced Memory Protection Unit (NMPU) further protect memory against erroneous transfers.

The Error Signaling Module (ESM) monitors all device errors and determines whether an interrupt or external Error pin/ball is triggered when a fault is detected. The nERROR can be monitored externally as an indicator of a fault condition in the microcontroller.



The External Memory Interface (EMIF) provides a memory extension to asynchronous and synchronous memories or other slave devices.

Several interfaces are implemented to enhance the debugging capabilities of application code. In addition to the built in ARM® Cortex®-R5F CoreSight™ debug features. Embedded Cross Trigger (ECT) supports the interaction and synchronization of multiple triggering events within the SoC. An External Trace Macrocell (ETM) provides instruction and data trace of program execution. For instrumentation purposes, a RAM Trace Port Module (RTP) is implemented to support high-speed tracing of RAM and peripheral accesses by the CPU or any other master. A Data Modification Module (DMM) gives the ability to write external data into the device memory. Both the RTP and DMM have no or only minimum impact on the program execution time of the application code. A Parameter Overlay Module (POM) is included to enhance the calibration capabilities of application code. The POM can re-route Flash accesses to internal memory or to the EMIF, thus avoiding the re-programming steps necessary for parameter updates in Flash.

With integrated safety features and a wide choice of communication and control peripherals, the TMS570LC43x is an ideal solution for high performance real time control applications with safety critical requirements.

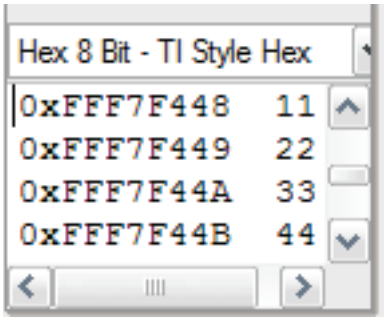
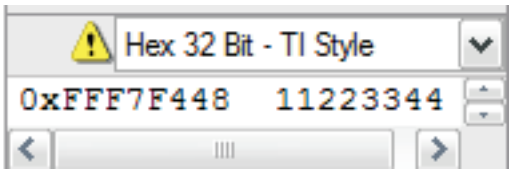
1.3 Endianism Considerations



1.3.1 TMS570: Big Endian (BE32)



The TMS570LC43x family is based on the ARM® Cortex®-R5F core. ARM has designed this core to be used in big-endian and little-endian systems. For the TI TMS570LC43x family, the endianness has been configured to BE32. Big-endian systems store the most-significant byte of a multi-byte data field in the lowest memory address. Also, the address of the multi-byte data field is the lowest address. Following is an example of the physical addresses of individual bytes.

Figure 1-2. Example: SPIDELAY – 0xFFF7F448

31 24	23 16
C2TDELAY[7:0]	T2CDELAY[7:0]
Byte 3 - 0xFFF7F448	Byte 2 - 0xFFF7F449
15 8	**7 0**
T2EDELAY[7:0]	C2EDELAY[7:0]
Byte 1 - 0xFFF7F44A	Byte 0 - 0xFFF7F44B

32-bit accesses to this register should use the lowest address, that is, 0xFFF7F448. Writing 0x11223344 to address 0xFFF7F448 shows the following when viewing the memory in 8-bit and 32-bit modes.

As such the headers provided as part of HALCoGen do take the endianness into account and provide header structures that are agnostic to endianness. This is achieved by using C directives for the compiler that make use of the compile options configured for the project by the user (__little_endian__ used in Code Composer Studio codegen tools). This directive may need to be adapted for other compilers.

```
#ifdef __little_endian__
    char  C2EDELAY      :  8U;  /**lt; 0xF448: CS to ENA        */
    char  T2EDELAY      :  8U;  /**lt; 0xF449: Transmit to ENA  */
    char  T2CDELAY      :  8U;  /**lt; 0xF44A: Transmit to CS   */
    char  C2TDELAY      :  8U;  /**lt; 0xF44B: CS to Transmit   */
#else
    char  C2TDELAY      :  8U;  /**lt; 0xF448: CS to Transmit   */
    char  T2CDELAY      :  8U;  /**lt; 0xF449: Transmit to CS   */
    char  T2EDELAY      :  8U;  /**lt; 0xF44A: Transmit to ENA  */
    char  C2EDELAY      :  8U;  /**lt; 0xF44B: CS to ENA        */
```

Architecture

This chapter consists of five sections. The first section describes specific aspects of the device architecture. The second section describes the clocking structure of the microcontrollers. The third section gives an overview of the device memory organization. The fourth section details exceptions on the device, and the last section describes the system and peripheral control registers of the microcontroller.

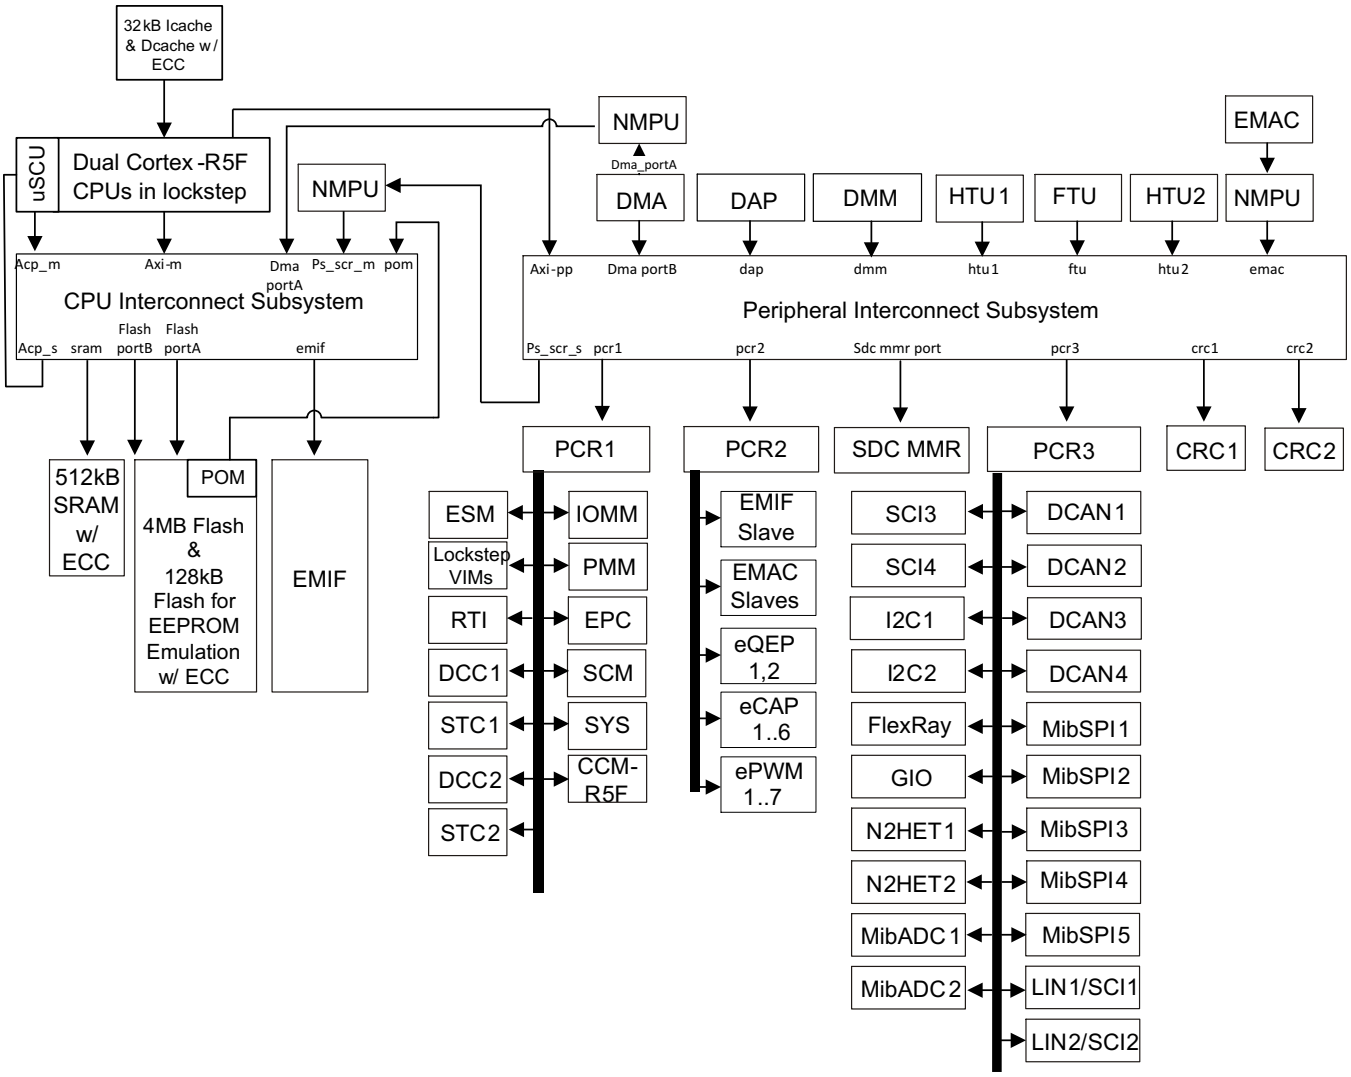
2.1 Introduction

The TMS570LC43x family of microcontrollers is based on the Texas Instruments TMS570 Architecture. This chapter describes specific aspects of the architecture as applicable to the TMS570LC43x family of microcontrollers.



2.1.1 Architecture Block Diagram

The TMS570LC43x microcontrollers are based on the TMS570 Platform architecture, which defines the interconnect between the bus masters and the bus slaves. The architecture consists of two main interconnects which connect all the masters and slaves together. The separation of the two interconnects creates a concept of two safety islands. The CPU safety island consists of the CPU Interconnect Subsystem which glues the masters and slaves together. The CPU safety island contains high degree of safety diagnostics on the bus system and the memories. Memories and buses are protected by means of ECC on the data path using Single-Bit Correction Double-Bit Detection (SECDED) scheme. Parity detection scheme is used on all address and control paths between all masters and slaves. Safety diagnostic logic is built into the CPU Interconnect Subsystem where all traffics going in and out are checked against their expected behaviors during application runtime. In addition, self-test logic is built into the CPU Interconnect Subsystem which can be enabled to diagnose possible faults. The Peripheral safety island consists of the Peripheral Interconnect Subsystem which glues the rest of the masters and slaves in the device. Diagnostic on the peripheral island is by means of ECC or parity protection on the peripheral memories and MPU protection.

Figure 2-1 shows a high-level architectural block diagram for the microcontroller.

2.1.2 Definitions of Terms

Table 2-1 provides a definition of terms used in the architectural block diagram.

Table 2-1. Definition of Terms

Acronym/Term	Full Form	Description
ADCx	Analog-to-Digital Converter	The ADC uses the Successive Approximation Register architecture. It features a selectable 10-bit or 12-bit resolution. The ADC module also includes a RAM to hold the conversion results. A digital logic wrapper manages accesses to the control and status registers. There are two ADC modules on this device.
CCM-R5F	CPU Compare Module for Cortex-R5F core	During lockstep mode, the outputs of the two CPUs are compared on each CPU clock cycle by this module. Any miscompare is flagged as an error of the highest severity level. The outputs of the two VIMs in lockstep are also compared on each cycle by this module.
Cortex-R5F CPU	–	The Cortex-R5F has one AXI-M master port on the CPU Interconnect Subsystem and another AXI-PP peripheral port on the peripheral Interconnect Subsystem for low latency access. Each master port is limited to accesses on the resources attached to the respective interconnect.
CPU Interconnect Subsystem	CPU Side Switched Central Resource Controller	This is one of the two main SCRs in the device. It arbitrates between the accesses from multiple bus masters to the bus slaves using a round robin priority scheme. This interconnect subsystem contains diagnostic logic to perform parity checking on address and control signals from bus masters, parity checking on response signals from slaves, ECC generation and evaluation on the datapath for transactions initiated by the non-CPU masters and also self test logic to diagnose itself.
CRCx	Cyclic Redundancy Checker	The CRC module provides two channels to perform background signature verification on any memory region using a 64-bit maximum-length linear feedback shift register (LFSR) . The CRC module is a bus slave in this device.
DAP	Debug Access Port	The DAP allows a tool such as a debugger to read from or write to any region in the device memory-map. The DAP is a bus master in this device.
DCANx	Controller Area Network controller	The DCAN supports the CAN 2.0B protocol standard and uses a serial, multi-master communication protocol that efficiently supports distributed real-time control with robust communication rates of up to 1 megabit per second (Mbps). The DCAN is ideal for applications operating in noisy and harsh environments (for example, automotive and industrial fields) that require reliable serial communication or multiplexed wiring.
DCCx	Dual Clock Comparator	This module is primarily intended for use to determine the accuracy of a clock signal during the execution of an application. An additional use of this module is to measure the frequency of a selectable clock source, using the input clock as a reference.
DMA	Direct Memory Access	The DMA module is used for transferring 8-, 16-, 32- or 64-bit data across the entire device memory-map. The DMA module is one of the bus masters on the device. That is, it can initiate a read or a write transaction. DMA has two master ports with DMA_PortA and DMA_PortB. DMA_PortA is connected to the CPU Interconnect Subsystem and DMA_PortB is connected to the Peripheral Interconnect Subsystem. DMA can transfer data from resources in CPU Interconnect Subsystem to resources in the Peripheral Interconnect Subsystem and vice versa.
DMM	Data Modification Module	The DMM allows a tool to use the special DMM I/O interface to modify any data value in any RAM on the device. The modification is done with minimal interruption to the application execution, and can be used for calibration of application algorithms. the DMM is also a bus master in this device.
eCAP	Enhanced Capture Module	The enhanced Capture (eCAP) module is essential in systems where accurate timing of external events is important.
eFuse	Electronically Programmable Fuse controller	Electrically programmable fuses (eFuses) are used to configure the device after deassertion of PORRST. The eFuse values are read and loaded into internal registers as part of the power-on-reset sequence. The eFuse values are protected with Single-Bit Error Correction Double-Bit Error Detection (SECDED) codes. These fuses are programmed during the initial factory test of the device. The eFuse controller is designed so that the state of the eFuses cannot be changed once the device is packaged.

Copyright © 2018, Texas Instruments Incorporated

Table 2-1. Definition of Terms (continued)

Acronym/Term	Full Form	Description
ePWM	Enhanced Pulse Width Modulator	The enhanced pulse width modulator (ePWM) peripheral is a key element in controlling many of the power electronic systems found in both commercial and industrial equipments. These systems include digital motor control, switch mode power supply control, uninterruptible power supplies (UPS), and other forms of power conversion. The ePWM peripheral performs a digital to analog (DAC) function, where the duty cycle is equivalent to a DAC analog value; it is sometimes referred to as a Power DAC.
eQEP	Enhanced Quadrature Encoder Pulse Module	The enhanced quadrature encoder pulse (eQEP) module is used for direct interface with a linear or rotary incremental encoder to get position, direction, and speed information from a rotating machine for use in a high-performance motion and position-control system.
ECC	Error Correction Code	This is a code that is used by the Single-Bit Error Correction Double-Bit Error Detection (SECDED) logic inside the two Cortex-R5F processors (CPUs) and various modules that support ECC. Depending on the memory configuration, the number of ECC bits may vary. There are 8 bits of ECC for every 64 bits of data accessed from the CPU level 2 memory such as flash and RAM. CPU's level 1 cache system consists of instruction cache and data cache and each is additionally composed of data RAM, tag RAM or dirty RAM. The number of ECC bits used to protect these RAMs vary. Modules which support ECC protection on their local RAMs can also employ different number of ECC bits depending on the RAM's configuration. For example, DMA module use 9 bits of ECC to protect its local control packet memory.
EMAC	Ethernet Media Access Controller	The EMAC has a dedicated DMA-type component that is used to transfer data to / from the EMAC descriptor memory from / to another memory in the device memory-map. This DMA-type component of the EMAC is a bus master in this device.
EMAC slaves	Ethernet Media Access Controller slave ports	There are four EMAC slaves: 1. EMAC Control Module: this provides an interface between the EMAC and MDIO modules and the bus masters. It also includes 8KB of RAM to hold EMAC packet buffer descriptors. 2. EMAC: The EMAC module interfaces to the other devices on the Ethernet Network using the Media Independent Interface (MII) or Reduced Media Independent Interface (RMII). 3. Management Data Input / Output (MDIO): The MDIO module is used to manage the physical layer (PHY) device connected to the EMAC module. 4. Communications Port Programming Interface (CPPI): This is the 8KB of RAM used to hold the EMAC packet buffer descriptors.
EMIF slaves	External Memory Interface slave ports	There are five EMIF slaves: • External SDRAM memory: EMIF chip select 0 • External asynchronous memories: EMIF chip selects 2, 3 and 4 • EMIF module control and status registers
EPC	Error Profiling Controller	This module is used to profile the occurrences of single-bit and double-bit ECC errors detected by the CPU and the CPU Interconnect Subsystem.
ESM	Error Signal Module	ESM collects and reports the various error conditions on the device. The error condition is categorized based on a severity level. Error response is then generated based on the category of the error. Possible error responses include a low priority interrupt, high priority NMI interrupt and an external pin action.
Flash Memory	Level 2 Flash Memory	There are two slave ports (Flash_PortA and Flash_PortB) to access the flash memory consisting of three flash banks. The two ports allow two masters to access among the three banks in parallel. There are two 2Mbyte banks and one EEPROM bank. The EEPROM bank is a flash bank that is dedicated for use as an emulated EEPROM. This device supports 128KB of flash for emulated EEPROM.
FlexRay	FlexRay communication controller	The FlexRay uses a dual channel serial, fixed time base multi-master communication protocol with communication rates of 10 megabits per second (Mbps) per channel.
FTU	FlexRay Transfer Unit	The FTU is a dedicated transfer unit for the FlexRay communication interface controller. The FTU has a native interface to the FlexRay message RAM and is used to transfer data to / from the FlexRay message RAM from / to another region in the device memory-map. The FTU is a bus master in this device.
GIO	General-purpose Input/Output	The GIO module allows up to 16 terminals to be used as general-purpose Input or Output. Each of these are also capable of generating an interrupt to the CPU.

Copyright © 2018, Texas Instruments Incorporated

Table 2-1. Definition of Terms (continued)

Acronym/Term	Full Form	Description
HTUx	High-end timer Transfer Unit	The HTU is a dedicated transfer unit for the New Enhanced High-End Timer module. The HTU has a native interface to the N2HET RAM, and is used to transfer data to / from the N2HET RAM from / to another region in the device memory-map. There is one HTU per N2HET module, so that there are 2 HTU modules on the device. The HTUx are bus masters in this device.
I2Cx	Inter-Integrated Circuit controller	The I2C module is a multi-master communication module providing an interface between the device and an I2C-compatible device via the I2C serial bus. The I2C supports both 100 Kbps and 400 Kbps speeds.
IOMM	IO Multiplexing Module	This module controls the multiplexing on the device I/Os. Multiple functions can be multiplexed onto the same device IO. Through IOMM module, user can enable a specific function onto a device pin.
LINx	Local Interconnect Network controller	The LIN module supports the Local Interconnect standard revision 2.1 and can be used as a UART in full-duplex mode using the standard Non-Return-to-Zero (NRZ) format.
Lockstep	–	This is the mode of operation of the dual ARM Cortex-R5F CPUs. The outputs of the two CPUs are compared on each CPU clock cycle. Any miscompare is flagged as an error of the highest severity level. In addition to the lockstep CPUs, the two Vector Interrupt Module (VIM) are also in lockstep.
MibSPIx	Multi-Buffered Serial Peripheral Interface	The MibSPIx modules also support the standard SPI communication protocol. The transfers are all grouped into transfer chunks called “transfer groups”. These transfer groups are made up of one ore more buffers in the MibSPIx RAM. The RAM is used to hold the control information and data to be transmitted, as well as the status information and data that is received. There are five MibSPI modules in this device.
N2HETx	New Enhanced High-End Timer	The N2HET is an advanced intelligent timer that provides sophisticated timing functions for real-time applications. The timer is software-controlled, using a reduced instruction set, with a specialized timer micromachine and an attached I/O port. The N2HET can be used for pulse width modulated outputs, capture or compare inputs, or general-purpose I/O.
NMPUx	Enhanced Memory Protection Unit	There are three standalone NMPUs on this device protecting memory transactions initiated by DMA, EMAC and other masters onto the resources on the device. In this device, all transactions initiated by non-CPU masters will go through two levels of MPU protection. The two levels can be a combination of two NMPU in series or one standalone NMPU and one build-in MPU as part of the master. One NMPU is dedicated to the DMA port connecting to the CPU Interconnect Subsystem as the second level protection while the built-in MPU inside the DMA acts as the first level protection. HTUx and FTU all have their built-in MPU acting as the first level protection. All accesses initiated by the masters on the Peripheral Interconnect Subsystem side will funnel through another NMPU sitting in between the path connecting the Peripheral Interconnect Subsystem to the CPU Interconnect Subsystem. This will act as the second level protection for HTUx, FTU and EMAC. EMAC does not have the built-in MPU and hence a standalone NMPU is instantiated between the EMAC and the interconnect.
Peripheral Interconnect Subsystem	Peripheral Side Switched Central Resource Controller	This is one of the two main SCRs in the device. It arbitrates between the accesses from multiple bus masters to the bus slaves using a round robin priority scheme.
PCRx	Peripheral Central Resource controller	The PCR manages the accesses to the peripheral registers and peripheral memories. It provides a global reset for all the peripherals. It also supports the capability to selectively enable or disable the clock for each peripheral individually. The PCR also manages the accesses to the system module registers required to configure the device’s clocks, interrupts, and so on. The system module registers also include status flags for indicating exception conditions – resets, aborts, errors, interrupts. This device has three PCR modules with each capable to access different peripherals as shown in the block diagram. The three PCRs are slaves to the Peripheral Interconnect Subsystem.
PMM	Power Management Module	This module controls the clock gating to the various logic power domains in the device. Through PMM, user can place a power domain among Active, Idle or Off modes. This device does not implement physical power domains in which power can be turned off. Trying to turn off a power domain has no effect on this device in terms of power consumption but clocks will be gated off to remove dynamic power. Idle and Off modes in this device behave the same from power consumption perspective.

Table 2-1. Definition of Terms (continued)

Acronym/Term	Full Form	Description
POM	Parameter Overlay Module	The parameter overlay module redirects accesses to a programmable region in flash memory (read-only) to a RAM memory, either on-chip or via the external memory interface (EMIF). This allows a user to evaluate the impact of changing values of constants stored in the flash memory without actually having to erase and reprogram the flash. The POM is also a bus master in this device.
PS_SCR_M	Peripheral SCR Master Port	All transactions to access the resources in the CPU Interconnect Subsystem by HTUx, FTU, EMAC, DMM and DAP will funnel through the PS_SCR_S slave port on the Peripheral Interconnect Subsystem. The PS_SCR_S slave is then connected to the PS_SCR_M master port on the CPU Interconnect Subsystem via a NMPU in between.
RTI	Real Time Interrupt module	RTI module provides timer functionality for operating systems and for benchmarking code. The module incorporates several counters, which define the timebases needed for scheduling in the operating system.
SCIx	Serial Communication Interface	The SCI module supports the standard UART in full-duplex mode using the standard Non-Return-to-Zero (NRZ) format.
SCM	SCR Control Module	This module is used to change certain configurations such as timeout counters of the CPU Interconnect Subsystem. This module is also used to initiate selftest for the CPU Interconnect Subsystem.
SDC MMR	Safety Diagnostic Checker Memory-Map Register Port for CPU Interconnect Subsystem	There are memory-mapped status registers to record both the run-time and self-test diagnostic of the CPU Interconnect Subsystem. These registers are accessed via the SDC MMR slave port in the Peripheral Interconnect Subsystem.
SRAM	Level 2 Static RAM	There is one slave port to access the on-chip SRAM.
STCx	Selftest Controller	There are two STC modules in this device. One is used to test the CPU subsystem including both CPU cores and/or the ACP component using the Deterministic Logic Bist Controller as the test engine. The other STC is used to test either or both the N2HETs in the device.
SYS	System Module	This module contains the housekeeping logic to control and log overall system functions and status such as setting up the clock sources, clock domains, generation and reception of reset sources.
µSCU	Micro Snooping Control Unit	The µSCU which is part of the Cortex-R5 processor system contains an ACP (Accelerator Coherency Port) interface which provides snoop capabilities on write-transactions coming from the non-CPU masters. Transactions are received on the ACP-S slave port, and transmitted on the memory system via the ACP-M master port. The ACP automatically invalidates the appropriate Level 1 data-cache lines at the appropriate time, allowing software maintenance free cache coherency for data in write-through cache regions, as well as non-cached.
VIM	Vectored Interrupt Manager	VIM provides hardware assistance for prioritizing and controlling the many interrupt sources present on a device. There are two VIMs in this device. When the device is configured in lockstep mode, the two VIMs are also in lockstep. The outputs of the two VIMs are compared cycle by cycle by the CCM-R5 module.

2.1.3 Bus Master / Slave Access Privileges

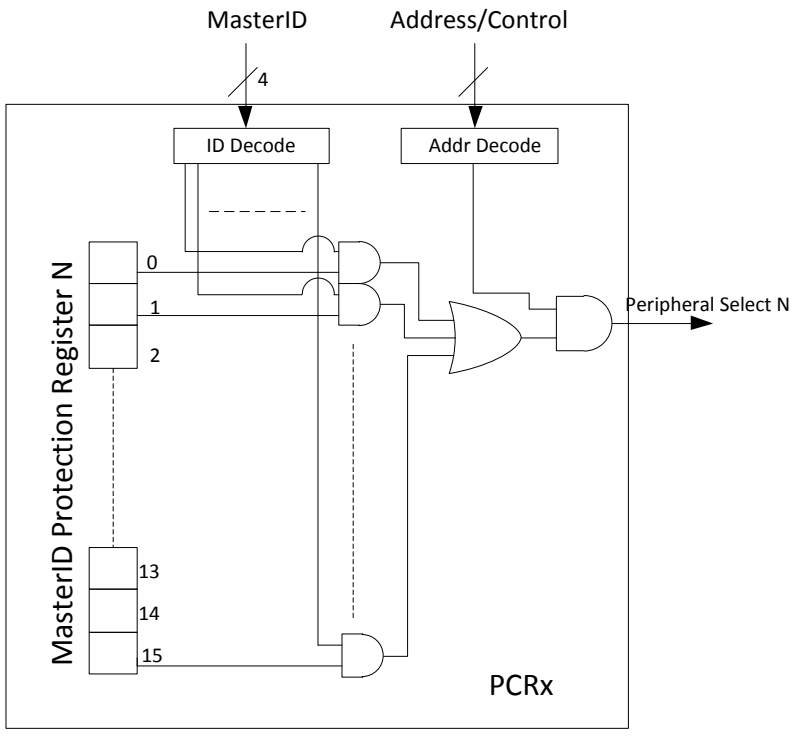
This device implements some restrictions on the bus slave access privileges in order to improve the overall throughput of the interconnect shown in Figure 2-1. Table 4-1 shows the implemented point to point connections between the masters and slaves connected to the Peripheral Interconnect Subsystem. Table 4-3 lists the implemented point to point connections between the masters and slaves connected to the CPU Interconnect Subsystem.

2.1.4 CPU Interconnect Subsystem SDC MMR Port

The CPU Interconnect Subsystem SDC MMR Port is a special slave to the Peripheral Interconnect Subsystem. It is memory-mapped at starting address of FA00 0000h. Various status registers pertaining to the diagnostics of the CPU Interconnect Subsystem can be access through this slave port. The CPU Interconnect Subsystem contains built-in hardware diagnostic checkers which will constantly watch transactions flowing through the interconnect. There is a checker for each master and slave attached to the CPU Interconnect Subsystem. The checker checks the expected behavior against the generated

Copyright © 2018, Texas Instruments Incorporated

behavior by the interconnect. For example, if the CPU issues a burst read request to the flash, the checker will ensure that the expected behavior is indeed a burst read request to the proper slave module. If the interconnect generates a transaction which is not a read, or not a burst or not to the flash as the destination, then the checker will flag it in one of the registers. The detected error will also be signaled to the ESM module. Table 4-2 lists the CPU Interconnect Subsystem SDC register bit field mapping.



2.1.5 Interconnect Subsystem Runtime Status

Other than the runtime checker status as described in Section 2.1.4, the CPU Interconnect Subsystems and the Peripheral Interconnect Subsystem in the microcontroller also generates several status onto the system that are captured in the SCM (SCR Control Module). Table 4-4 lists the SCM register bit mapping.

2.1.6 Master ID to PCRx

The master ID associated with each master port on the Peripheral Interconnect Subsystem contains a 4-bit value. The master ID is passed along with the address and control signals to three PCR modules. PCR decodes the address and control signals to select the peripheral. In addition, it decodes this 4-bit master ID value to perform memory protection. With 4-bit of master ID, it allows the PCR to distinguish among 16 different masters to allow or dis-allow access to a given peripheral. Associated with each peripheral a 16-bit Master ID access protection register is defined. Each bit grants or denies the permission of the corresponding binary coded decimal masterID. For example, if bit 5 of the access permission register is set, it grants master ID 5 to access the peripheral. If bit 7 is clear, it denies master ID 7 to access the peripheral. Figure 2-2 illustrates the Master-ID filtering scheme. The master ID of each master that is capable of accessing the PCRx is listed in Table 4-1. Also see Section 2.5.3 for details on the registers definition.

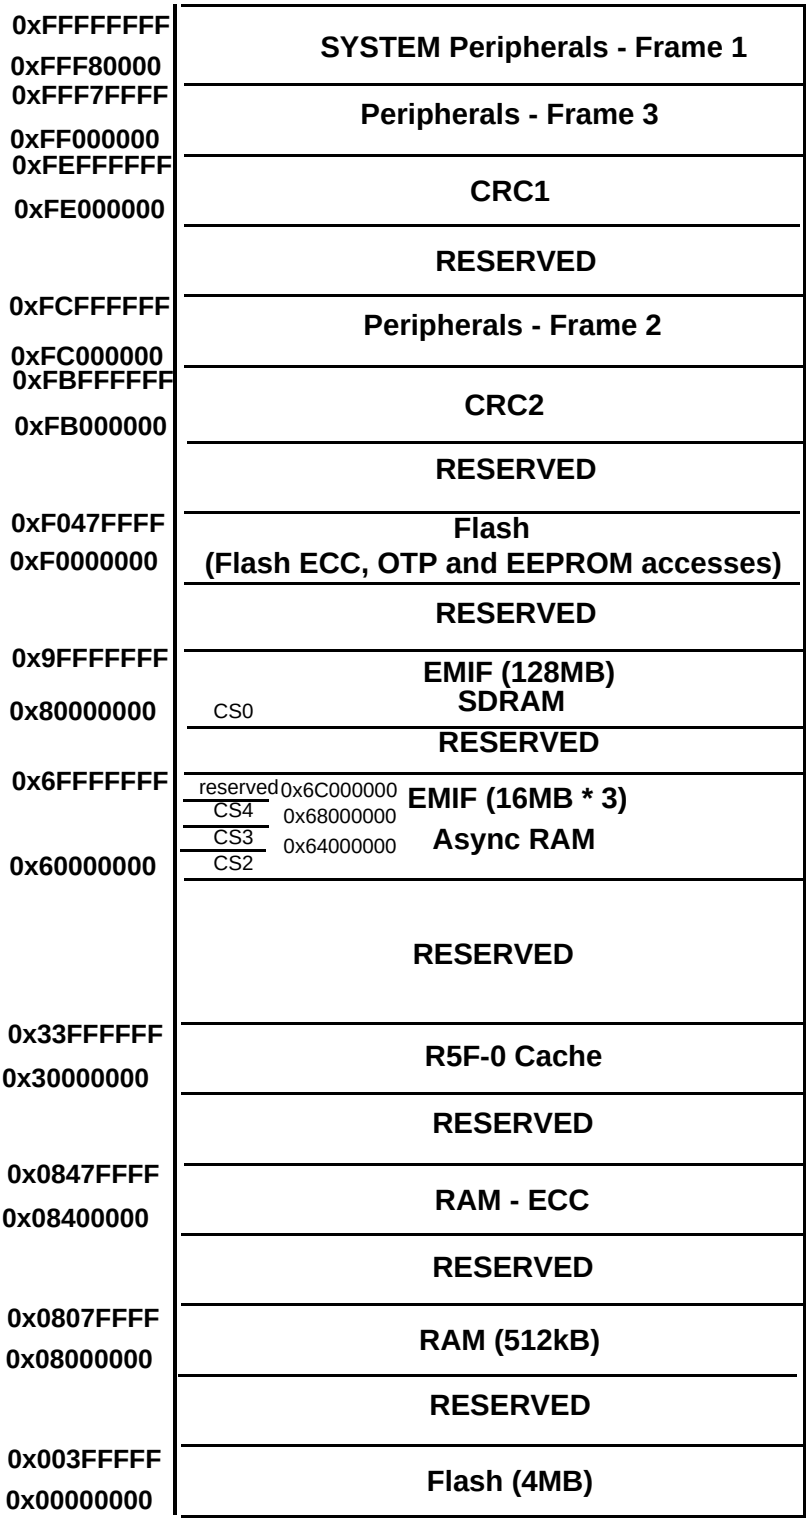
2.2 Memory Organization

2.2.1 Memory-Map Overview

The Cortex-R5F uses a 32-bit address bus, giving it access to a memory space of 4GB. This space is divided into several regions, each addressed by different memory selects. Figure 2-3 shows the memory-map of the microcontroller.

The main flash instruction memory is addressed starting at 0x00000000 by default. This is also the reset vector location – the ARM Cortex-R5F processor core starts execution from the reset vector address of 0x00000000 whenever the core gets reset.

The CPU data RAM is addressed starting at 0x08000000 by default.



The device also supports the swapping of the CPU instruction memory (flash) and data memory (RAM). This can be done by configuring the MEM SWAP field of the Bus Matrix Module Control Register 1 (BMMCR1).

After swapping, the data RAM is accessed starting from 0x00000000 and the RAM ECC locations are accessed starting from 0x00400000. The flash memory is now accessed starting from 0x08000000.

NOTE: After the swap with the flash memory-mapped to 0x08000000, only 512kB of the flash memory from 0x08000000 to 0x0807FFFF will be accessible by the bus masters.

2.2.2 Memory-Map Table

The control and status registers for each module are mapped within the CPU's 4GB memory space. Some modules also have associated memories, which are also mapped within this space.

Table 2-2 shows the starting and ending addresses of each module's register frame and any associated memory. The table also shows the response generated by the module or the interconnect whenever an access is made to an unimplemented location inside the register or memory frame.

Table 2-2. Module Registers / Memories Memory-Map

Target Name	Memory Select	Address Range		Frame Size	Actual Size	Response for Access to Unimplemented Locations in Frame
		Start	End			
Level 2 Memories						
Level 2 Flash Data Space		0x0000_0000	0x003F_FFFF	4MB	4MB	Abort
Level 2 SRAM		0x0800_0000	0x083F_FFFF	4MB	512kB	Abort

2.2.3 Flash on Microcontrollers

The TMS570LC43x microcontrollers support up to 4 MB of flash for use as program memory. The microcontrollers also support a separate 128kB flash bank for use as emulated EEPROM.

Refer to the device data manual for electrical and timing specifications related to the flash module.

2.2.3.1 Flash Bank Sectoring Configuration

The bank is divided into multiple sectors. A flash sector is the smallest region in the flash bank that must be erased. The sectoring configuration of each flash bank is shown in Table 2-3.

- The Flash banks are 288-bit wide bank with ECC support.
- The flash bank7 can be programmed while executing code from flash bank0.
- Code execution is not allowed from flash bank7.

Copyright © 2018, Texas Instruments Incorporated

Table 2-3. Flash Memory Banks and Sectors

Sector Number	Sector Size	Low Address	High Address
Bank 0: 2.0 MBytes			
0	16K Bytes	0x0000_0000	0x0000_3FFF
1	16K Bytes	0x0000_4000	0x0000_7FFF

2.2.3.2 ECC Protection for Flash Accesses

The TMS570LC43x microcontrollers protect all accesses to the on-chip level 2 flash memory by dedicated Single-Bit Error Correction Double-Bit Error Detection (SECDED) logic.

The access to the program memory – flash bank 0, 1 and 7 are protected by SECDED logic implemented inside the ARM Cortex-R5F CPU.

The SECDED logic implementation uses Error Correction Codes (ECC) for correcting single-bit errors and for detecting multiple-bit errors in the values read from the flash arrays. There is an 8-bit ECC for every 64 bits of data. The ECC for the level 2 flash memory contents needs to be calculated by an external tool such as nowECC. The ECC can then be programmed into the flash array along with the actual application code.

The ECC for the flash array is stored in the flash itself, and is mapped to a region starting at 0xF0400000 for the main flash bank 0 and 1, and to a region starting at 0xF0100000 for the EEPROM emulation flash bank 7.

NOTE: The SECDED logic inside the CPU is permanently enabled for the AXI-M and AXI-S interfaces.

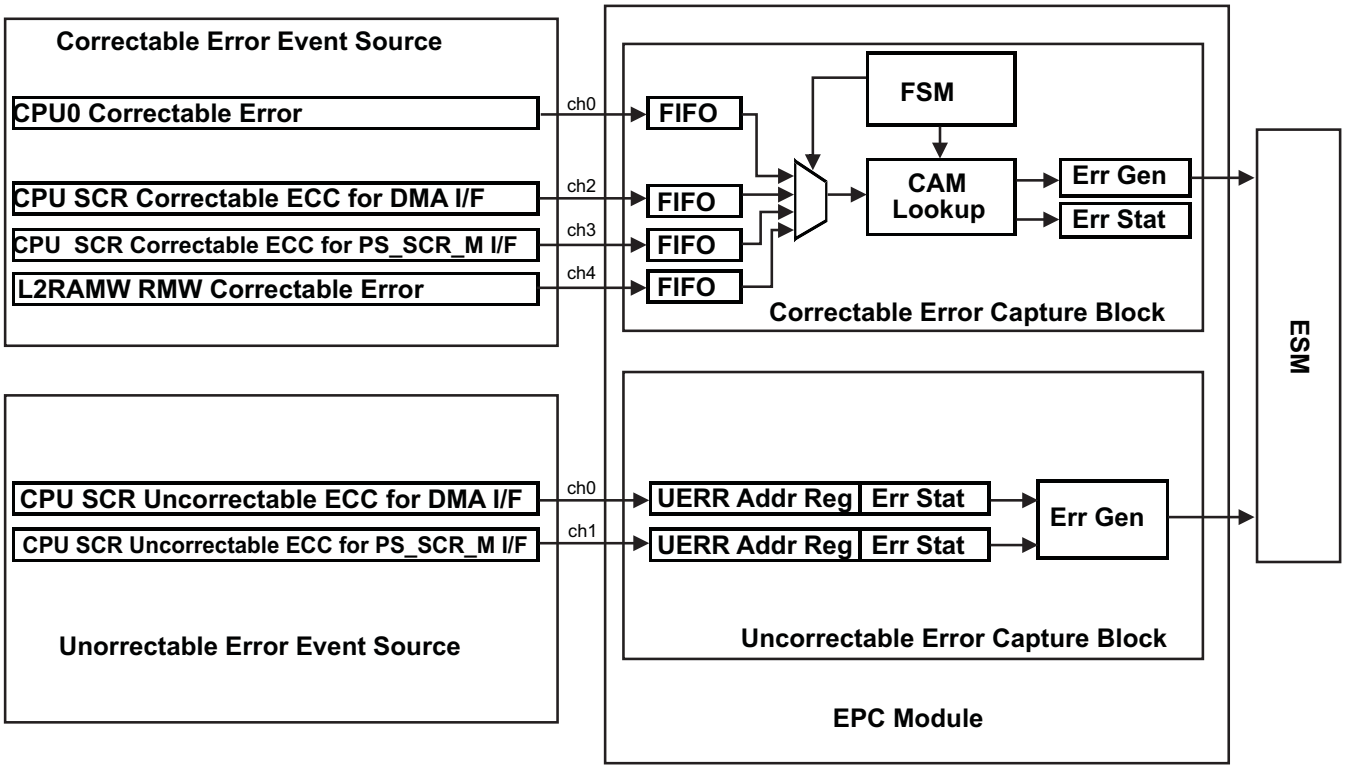
Code Example for Enabling ECC Protection for Main Flash Accesses:

When the CPU detects an ECC single-, or double-bit error on a read from the flash memory, it signals this on a dedicated "*Event*" bus. This event bus signaling is also not enabled by default and must be enabled by the application. The below code example can be used to enable the CPU event signaling.

```
MRC p15,#0,r1,c9,c12,#0       ;Enabling Event monitor states
ORR r1, r1, #0x00000010
MCR p15,#0,r1,c9,c12,#0       ;Set 4th bit ('X') of PMNC register
MRC p15,#0,r1,c9,c12,#0
```

The ECC error events exported onto the *Event* bus is first captured by the Error Profiling Controller (EPC) module and in turn generates error signals that are input to the central Error Signaling Module (ESM).

2.2.3.3 Error Profiling Module (EPC)



The main idea of EPC is to enable the system to tolerate a certain amount of ECC correctable errors on the same address repeatedly in the memory system with minimal runtime overhead. EPC will record different single-bit error addresses in a Content Addressable Memory (CAM). If a correctable ECC error is generated on a repeating address, the EPC will not raise an error to ESM module. This tolerance avoids the application to handle the same error when the code is in a repeating loop. There are 4correctable error interfaces implemented in EPC to capture correctable errors from 4 different sources. There are also 2 uncorrectable error interfaces implemented in EPC to capture uncorrectable errors from 2 different sources. Main features of EPC are:

- Capture the addresses of the correctable ECC faults from different sources such as CPU cores, L2 SRAM and interconnect into a 32-entry CAM (Content Addressable Memory)
- For correctable faults, the error handling depends on the following conditions:
  - if the incoming address is already in the 32-entry CAM, discard the fail. No error generated to ESM.
  - if the address is not in the CAM list, and the CAM has empty entries, add the address into the CAM list. In addition, raise the error signal to the ESM group 1 if enabled.
  - if the address is not in the CAM list, and the CAM has no empty entries, always raise the error signal to the ESM group 1.
- A 4-entry FIFO to store the correctable error events and addresses for each channel interface.
- For uncorrectable faults, capture the address and assert error signal to the ESM group 2.

Each EPC interface corresponds to a bit field in some of the EPC registers. Table 2-4 shows only those registers that associate the bits to a specific interface for this device. See EPC chapter for the full list of registers.

2.2.4 On-Chip SRAM

Several SRAM modules are implemented on the device to support the functionality of the modules included.

Reads from both the level 1 and level 2 SRAM are protected by ECC calculated inside the CPU. Reads from all other memories are protected by either the parity with configurable odd or even parity scheme or ECC that is evaluated in parallel with the actual read.

The TMS570LC43x microcontrollers are targeted towards safety-critical applications, and it is critical for any failures in the on-chip SRAM modules to be identified before these modules are used for safety-critical functions. These microcontrollers support a Programmable Built-In Self-Test (PBIST) mechanism that is used to test each on-chip SRAM module for faults. The PBIST is usually run on device start-up as it is a destructive test and all contents of the tested SRAM module are overwritten during the test.

The microcontrollers also support a hardware-based auto-initialization of on-chip SRAM modules. This process also takes into account the read protection scheme implemented for each SRAM module – ECC or parity.

TI recommends that the PBIST routines be executed on the SRAM modules prior to the auto-initialization. The following sections describe these two processes.

2.2.4.1 PBIST RAM Grouping and Algorithm Mapping For On-Chip SRAM Modules

Table 2-5 shows the groupings of the various on-chip memories for PBIST. It also lists the memory types and their assigned RAM Group Select (RGS) and Return Data Select (RDS). Refer to the PBIST chapter for more details on the usage of the RGS and RDS information.

Table 2-5. PBIST Memory Grouping

Module	RAM Group #	RGS	RDS	Memory Type
PBIST_ROM	1	1	1	ROM

Table 2-6 maps the different algorithms supported in application mode for the RAM groups. The table also lists the background pattern options available for each algorithm.

Table 2-6. PBIST Algorithm Mapping

Sr. No.	ALGO Register Value	Algorithm	Memories Under Test	Available Background Patterns	Valid RAM Groups	Valid RINFOL/RINFOU Register Value
1	0x00000001	triple_read_slow_read	ROM		1,2,3,4	0x0000000F/ 0x00000000
2	0x00000002	triple_read_fast_read	ROM		1,2,3,4	0x0000000F/ 0x00000000
3	0x00000004	march13n	Two-port	0x00000000, 0x96699669, 0x0F0F0F0F, 0xAA55AA55, 0xC3C3C3C3	5,6,7,8,9,10,11,12,13, 14,16,17,18,19,20,21, 22,23,24,25,26,27,28	0x0FFFBFF0/ 0x00000000
4	0x00000008	march13n	Single-port	0x00000000, 0x96699669, 0x0F0F0F0F, 0xAA55AA55, 0xC3C3C3C3	29,30,31,32,35,36,37	0xF0000000/ 0x0000001C

NOTE: Recommended Memory Test Algorithm

March13 is the most recommended algorithm for the memory self-test.

For GCLK1 = 300 MHz, HCLK = 150 MHz, VCLK = 75 MHz, PBIST ROM_CLK = 75 MHz, the March13 algorithm takes about 29.08 ms to run on all on-chip SRAMs.

NOTE: PBIST ROM_CLK can be prescaled from GCLK1 via ROM_DIV bits of the MSTGCR register. The valid ratio is either /1, /2 or /4 or /8. See Section 2.5.1.20 for detail. Maximum PBIST ROM_CLK frequency supported is 82.5MHz.

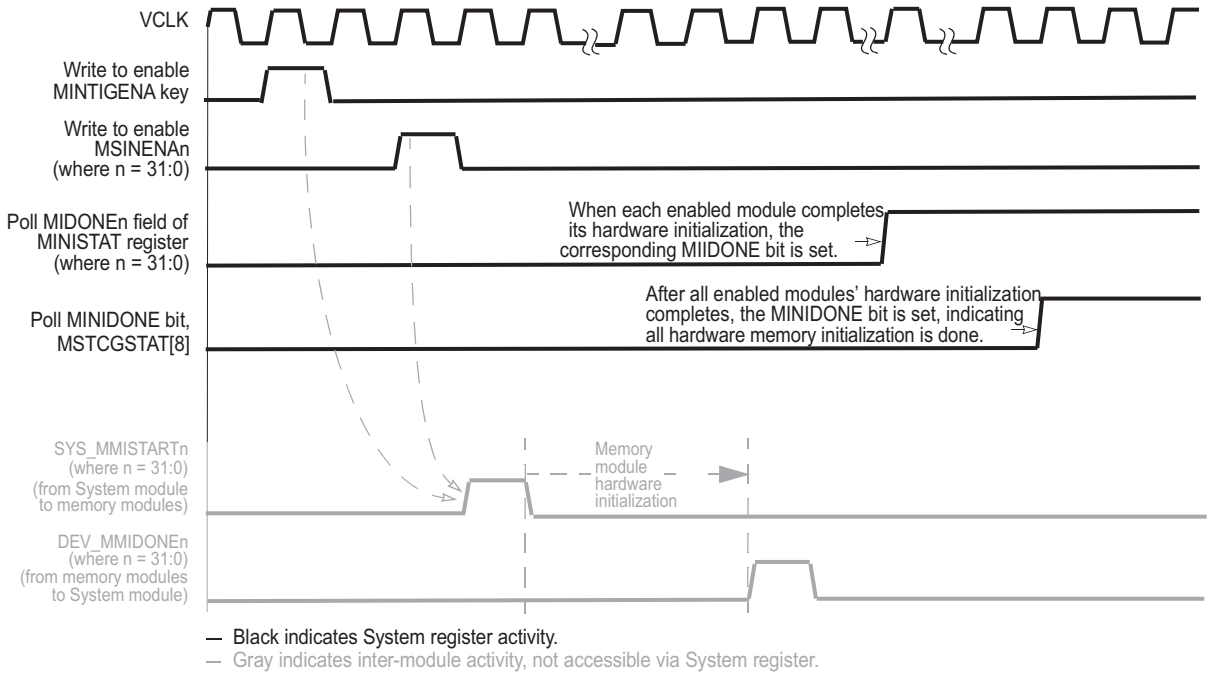
2.2.4.2 Auto-Initialization of On-Chip SRAM Modules

The device system provides the capability to perform a hardware initialization on most memories on the system bus and on the peripheral bus. The memory used for the FlexRay message objects is ECC protected but is not directly CPU addressable, hence there is no memory auto-initialization support for this memory.

The intent of having the hardware initialization is to program the memory arrays with error detection capability to a known state based on their error detection scheme – odd/even parity or ECC. For example, the contents of the CPU level 2 SRAM after power-on reset is unknown. A hardware auto-initialization can be started so that there is no ECC error.



NOTE: Effect of ECC or Parity on Memory Auto-Initialization

The ECC or parity should be enabled on the RAMs before hardware auto-initialization starts if parity or ECC is being used.

Auto-Initialization Sequence:

1. Enable the global hardware memory initialization key by programming 0xA into MINITGCR[3:0], the Memory Initialization Key field (MINITGENA) of the Memory Hardware Initialization Global Control Register (MINITGCR) register.
2. Select the module on which the memory hardware initialization has to be performed by programming the appropriate value into the MSINENA(31–0) bits in the MSINENA register. See Table 2-7.
3. If the global auto-initialization scheme is enabled, the corresponding module will initialize its memories based on its memory error checking scheme (even parity or odd parity or ECC).
4. When the memory initialization is complete, the module will signal “memory initialization done”, which sets the corresponding bit in the system module MIDONE field of the MINISTAT register to indicate the completion of its memory initialization.
5. When the memory hardware initialization completes for all modules, (indicated by each module’s MIDONE bit being set), the memory hardware initialization done bit (MINIDONE) is set in the MSTCGSTAT register.

Figure 2-5. Hardware Memory Initialization Protocol

FlexRay TU RAM	ECC	0xFF500000	0xFF51FFFF	13	n/a

(1) If parity protection is enabled for the peripheral SRAM modules, then the parity bits will also be initialized along with the SRAM modules.

(2) If ECC protection is enabled for the CPU data RAM or peripheral SRAM modules, then the auto-initialization process also initializes the corresponding ECC space.

(3) The level 2 SRAM range from 128kB to 512kB is divided into 6 memory regions. Each region has an associated control bit to enable auto-initialization.

(4) The MibSPIx modules perform an initialization of the transmit and receive RAMs as soon as the multi-buffered mode is enabled. This is independent of whether the application has already initialized these RAMs using the auto-initialization method or not. The MibSPIx modules need to be released from reset by writing 1 to their SPIGCR0 registers before starting auto-initialization on their respective RAMs.

2.3 Exceptions

An “Exception” is an event that makes the processor temporarily halt the normal flow of program execution, for example, to service an interrupt from a peripheral. Before attempting to handle an exception, the processor preserves the critical parts of the current processor state so that the original program can resume when the handler routine has finished.

The following sections describe three exceptions – Reset, Abort and the System Software Interrupts.

For complete details on all exceptions, refer to the ARM® Cortex®-R5F Technical Reference Manual.

2.3.1 Resets

The TMS570LC43x microcontroller can be reset by either of the conditions described in Table 2-8. Each reset condition is indicated in the System Exception Status Register (SYSESR).

The device nRST terminal is an I/O. It can be driven low by an external circuit to force a warm reset on the microcontroller. This terminal will be driven low as an output for a minimum of 32 peripheral clock (VCLK) cycles for any device system reset condition. As a result the EXTRST bit in the SYSESR register, SYSESR[3], gets set for all reset conditions listed in Table 2-8. The nRST is driven low as an output for a longer duration during device power-up or whenever the power-on reset (nPORRST) is driven low externally. Refer the device data manual for the electrical and timing specifications for the nRST.

Table 2-8. Causes of Resets

Condition	Description
Driving nPORRST pin low externally	Cold reset, or power-on reset. This reset signal is typically driven by an external voltage supervisor. This reset is flagged by the PORST bit in the SYSESR register, SYSESR[15].
Voltage Monitor reset	The microcontroller has an embedded voltage monitor that generates a power-on reset when the core voltage gets out of a valid range, or when the I/O voltage falls below a threshold. This reset is also flagged by the PORST bit in the SYSESR register, SYSESR[15]. **Note:** The voltage monitor is not an alternative for an external voltage supervisor.
Driving nRST pin low externally	Warm reset. This reset input is typically used in a system with multiple ICs and which requires that the microcontroller also gets reset whenever the other IC detects a fault condition. This reset is flagged by the EXTRST bit in the SYSESR, register SYSESR[3].
Oscillator failure	This reset is generated by the system module when the clock monitor detects an oscillator fail condition. Whether or not a reset is generated is also dictated by a register in the system module. This reset is flagged by the OSCRST bit in the SYSESR register, SYSESR[14].
Software reset	This reset is generated by the application software writing a 1 to bit 15 of System Exception Control Register (SYSECR) or a 0 to bit 14 of SYSECR. It is typically used by a bootloader type of code that uses a software reset to allow the code execution to branch to the application code once it is programmed into the program memory. This reset is flagged by the SWRST bit in the SYSESR register, SYSESR[4].
CPU reset	This reset is generated by the CPU self-test controller (LBIST) or by changing the memory protection (MMU/MPU) configuration in the CPURSTCR register or after the CPU Interconnect Subsystem self test. This reset is flagged by the CPURST bit in the SYSESR register, SYSESR[5].
Debug reset	The ICEPICK logic implemented on the microcontroller allows a system reset to be generated via the debug logic. This reset is flagged by the DBGRST bit in the SYSESR register, SYSESR[13].
Watchdog reset	This reset is generated by the digital windowed watchdog (DWWD) module on the microcontroller. The DWWD can generate a reset whenever the watchdog service window is violated. This reset is flagged by the WDRST bit in the SYSESR register, SYSESR[13].

2.3.2 Aborts

When the ARM Cortex-R5F processor's memory system cannot complete a memory access successfully, an abort is generated. An error occurring on an instruction fetch generates a ***prefetch abort***. Errors occurring on data accesses generate ***data aborts***. Aborts are also categorized as being either ***precise*** or ***imprecise***.

Copyright © 2018, Texas Instruments Incorporated

2.3.2.1 Prefetch Aborts

When a Prefetch Abort (PABT) occurs, the processor marks the prefetched instruction as invalid, but does not take the exception until the instruction is to be executed. If the instruction is not executed, for example because a branch occurs while it is in the pipeline, the abort does not take place.

All prefetch aborts are precise aborts.

2.3.2.2 Data Aborts

An error occurring on a data memory access can generate a data abort. If the instruction generating the memory access is not executed, for example, because it fails its condition codes, or is interrupted, the data abort does not take place.

A Data Abort (DABT) can be either precise or imprecise, depending on the type of fault that caused it.

2.3.2.3 Precise Aborts

A precise abort, also known as a synchronous abort, is one for which the exception is guaranteed to be taken on the instruction that generated the aborting memory access. The abort handler can use the value in the Link Register (r14_abt) to determine which instruction generated the abort, and the value in the Saved Program Status Register (SPSR_abt) to determine the state of the processor when the abort occurred.

2.3.2.4 Imprecise Aborts

An imprecise abort, also known as an asynchronous abort, is one for which the exception is taken on a later instruction to the instruction that generated the aborting memory access. The abort handler cannot determine which instruction generated the abort, or the state of the processor when the abort occurred. Therefore, imprecise aborts are normally fatal.

Imprecise aborts can be generated by store instructions to normal-type or device-type memory. When the store instruction is committed, the data is normally written into a buffer that holds the data until the memory system has sufficient bandwidth to perform the write access. This gives read accesses higher priority. The write data can be held in the buffer for a long period, during which many other instructions can complete. If an error occurs when the write is finally performed, this generates an imprecise abort.

The TMS570LC43x microcontroller architecture applies techniques at the system level to mitigate the impact of imprecise aborts. System level adoption of write status sidebands to the data path allow bus masters to comprehend imprecise aborts, turning them into precise aborts. In cases where this approach is not feasible, buffering bridges or other sources of imprecision may build a FIFO of current transactions such that an imprecise abort may be registered at the point of imprecision for later analysis.

Masking Of Imprecise Aborts:

The nature of imprecise aborts means that they can occur while the processor is handling a different abort. If an imprecise abort generates a new exception in such a situation, the banked link register (R14_abt) and the Saved Processor Status Register (SPSR_abt) values are overwritten. If this occurs before the data is pushed to the stack in memory, the state information about the first abort is lost. To prevent this from happening, the Current Processor Status Register (CPSR) contains a mask bit to indicate that an imprecise abort cannot be accepted, the A-bit. When the A-bit is set, any imprecise abort that occurs is held pending by the processor until the A-bit is cleared, when the exception is actually taken. The A-bit is automatically set when abort, IRQ or FIQ exceptions are taken, and on reset. The application must only clear the A-bit in an abort handler after the state information has either been stacked to memory, or is no longer required.

NOTE: Default Behavior for Imprecise Aborts

The A-bit in the CPSR is set by default. This means that no imprecise abort exception will occur. The application must enable imprecise abort exception generation by clearing the A-bit of the CPSR.

Copyright © 2018, Texas Instruments Incorporated

2.3.2.5 Conditions That Generate Aborts

An Abort is generated under the following conditions on the TMS570LC43x microcontrollers.

- Access to an illegal address (a non-implemented address)
- Access to a protected address (protection violation)
- Parity / ECC / Time-out Error on a valid access

Illegal Addresses:

The illegal addresses and the responses to an access to these addresses are defined in Table 2-2.

Addresses Protected By MPU:

For more details on the MPU configuration, refer to the ARM® Cortex®-R5F Technical Reference Manual.

A memory access violation is logged as a permission fault in the CPU's fault status register and the virtual address of the access is logged into the CPU's fault address register.

Protection of Peripheral Register and Memory Frames:

Accesses to the peripheral register and memory frames can be protected either by configuring the MPU or by configuring the Peripheral Central Resource (PCR) controller registers.

The PCR module PPROTSETx registers contain one bit per peripheral select quadrant. These bits define the access permissions to the peripheral register frames. If the CPU attempts to write to a peripheral register for which it does not have the correct permissions, a protection violation is detected and an Abort occurs.

Some modules also enforce register updates to only be allowed when the CPU is in a privileged mode of operation. If the CPU writes to these registers in user mode, the writes are ignored.

The PCR module PMPROTSETx registers contain one bit per peripheral memory frame. These bits define the access permissions to the peripheral memory frames. If the CPU attempts to write to a peripheral memory for which it does not have the correct permissions, a protection violation is detected and an Abort occurs.

NOTE: No Access Protection for Reads

The PCR PPROTSETx and PMPROTSETx registers protect the peripheral registers and memories against illegal writes by the CPU. The CPU can read from the peripheral registers and memories in both user and privileged modes.

2.3.3 System Software Interrupts

The system module provides the capability of generating up to four software interrupts. A software interrupt is generated by writing the correct key value to either of the four System Software Interrupt Registers (SSIRx). The SSI registers also allow the application to provide a label for that software interrupt. This label is an 8-bit value that can then be used by the interrupt service routine to perform the required task based on the value provided. The source of the system software interrupt is reflected in the system software interrupt vector (SSIVEC) register. The pending interrupt flag is captured in SSIF register.

NOTE: The SSIRx, SSIVEC and SSIF registers are banked registers. This allows the system module to support up to two CPUs for system software interrupt generation. Each CPU will have its own banked SSI registers. Both CPUs will see the SSI registers at the same address. The system module decodes the unique master ID corresponding to the CPU's access to the banked registers.

2.4 Clocks

This section describes the clocking structure of the TMS570LC43x microcontrollers.

2.4.1 Clock Sources

The devices support up to 7 clock sources. These are shown in Table 2-9. The electrical specifications as well as timing requirements for each of the clock sources are specified in the device data manual.

Table 2-9. Clock Sources

Clock Source #	Clock Source Name	Description
0	OSCIN	Main oscillator. This is the primary clock for the microcontroller and is the only clock that is input to the phase-locked loops. The oscillator frequency must be between 5 and 20 MHz.
1	PLL1	This is the output of the main PLL. The PLL is capable of modulating its output frequency in a controlled manner to reduce the radiated emissions.
2	Reserved	This clock source is not available and must not be enabled or used as source for any clock domain.
3	EXTCLKIN1	External clock input 1. A square wave input can be applied to this device input and used as a clock source inside the device.
4	LF LPO (Low-Frequency LPO) (CLK80K)	This is the low-frequency output of the internal reference oscillator. This is typically an 80 KHz signal (CLK80K) that is used by the real-time interrupt module for generating periodic interrupts to wake up from a low power mode.
5	HF LPO (High-Frequency LPO) (CLK10M)	This is the high-frequency output of the internal reference oscillator. This is typically a 10 MHz signal (CLK10M) that is used by the clock monitor module as a reference clock to monitor the main oscillator frequency.
6	PLL2	This is the output of the second PLL. There is no option of modulating this PLL's output signal. This separate non-modulating PLL allows the generation of an asynchronous clock source that is independent of the CPU clock frequency.
7	EXTCLKIN2	External clock input 2. A square wave input can be applied to this device input and used as a clock source inside the device.

2.4.1.1 Enabling / Disabling Clock Sources

Each clock source can be independently enabled or disabled using the set of Clock Source Disable registers – CSDIS, CSDISSET and CSDISCLR.

Each bit in these registers corresponds to the clock source number indicated in Table 2-9. For example, setting bit 1 in the CSDIS or CSDISSET registers disables the PLL#1.

NOTE: Disabling the Main Oscillator or HF LPO

By default, the clock monitoring circuit is enabled and checks for the main oscillator frequency to be within a certain range using the HF LPO as a reference. If the main oscillator and/or the HF LPO are disabled with the clock monitoring still enabled, the clock monitor will indicate an oscillator fault. The clock monitoring must be disabled before disabling the main oscillator or the HF LPO clock source(s).

The clock source is only disabled once there is no active clock domain that is using that clock source. Also check the "Oscillator and PLL" user guide for more information on enabling / disabling the oscillator and PLL.

On the TMS570LC43x microcontrollers, the clock sources 0, 4, and 5 are enabled by default.

Copyright © 2018, Texas Instruments Incorporated

2.4.1.2 Checking for Valid Clock Sources

The application can check whether a clock source is valid or not by checking the corresponding bit to be set in the Clock Source Valid Status (CSVSTAT) register. For example, the application can check if bit 1 in CSVSTAT is set before using the output of PLL#1 as the source for any clock domain.

2.4.2 Clock Domains

The clocking on this device is divided into multiple clock domains for flexibility in control as well as clock source selection. There are 10 clock domains on this device. Each of these are described in Table 2-10.

Each of the control registers listed in Table 2-10 are defined in Section 2.5. The AC timing characteristics for each clock domain are specified in the device data manual.

Table 2-10. Clock Domains

Clock Domain	Clock Disable Bit	Default Source	Source Selection Register	Special Considerations
GCLK1	CDDIS.0	OSCIN	GHVSRC[3:0]	• This the main clock from which HCLK is divided down • In phase with HCLK • Is disabled separately from HCLK via the CDDISx registers bit 0 • Can be divided by 1 up to 8 when running CPU self-test (LBIST) using the CLKDIV field of the STCCLKDIV register at address 0xFFFFE108
HCLK	CDDIS.1	OSCIN	GHVSRC[3:0]	• Divided from GCLK1 via HCLKCNTL register • Allowable clock ratio from 1:1 to 4:1 • Is disabled via the CDDISx registers bit 1
VCLK	CDDIS.2	OSCIN	GHVSRC[3:0]	• Divided down from HCLK via CLKCNTL register • Can be HCLK/1, HCLK/2,... or HCLK/16 • Is disabled separately from HCLK via the CDDISx registers bit 2 • HCLK:VCLK2:VCLK must be integer ratios of each other
VCLK2	CDDIS.3	OSCIN	GHVSRC[3:0]	• Divided down from HCLK • Can be HCLK/1, HCLK/2,... or HCLK/16 • Frequency must be an integer multiple of VCLK frequency • Is disabled separately from HCLK via the CDDISx registers bit 3
VCLK3	CDDIS.8	OSCIN	GHVSRC[3:0]	• Divided down from HCLK • Can be HCLK/1, HCLK/2,... or HCLK/16 • HCLK:VCLK3 must be integer ratios of each other • Is disabled separately from HCLK via the CDDISx registers bit 8
VCLKA1	CDDIS.4	VCLK	VCLKASRC[3:0]	• Defaults to VCLK as the source • Is disabled via the CDDISx registers bit 4
VCLKA2	CDDIS.5	VCLK	VCLKASRC[3:0]	• Defaults to VCLK as the source • Is disabled via the CDDISx registers bit 5
VCLKA4	CDDIS.11	VCLK	VCLKACON1[19:16]	• Defaults to VCLK as the source • Is disabled via the CDDISx registers bit 11
VCLKA4_DIVR	VCLKACON1.20	VCLK	VCLKACON1[19:16]	• Divided down from VCLKA4 using the VCLKA4R field of the VCLKACON1 register • Frequency can be VCLKA4/1, VCLKA4/2, ..., or VCLKA4/8 • Default frequency is VCLKA4/2 • Is disabled separately via the VCLKACON1 register's VCLKA4_DIV_CDDIS bit, if the VCLKA4 is not already disabled

Copyright © 2018, Texas Instruments Incorporated

Table 2-10. Clock Domains (continued)

Clock Domain	Clock Disable Bit	Default Source	Source Selection Register	Special Considerations
RTICLK1	CDDIS.6	VCLK	RCLKSRC[3:0]	• Defaults to VCLK as the source • If a clock source other than VCLK is selected for RTICLK1, then the RTICLK1 frequency must be less than or equal to VCLK/3 • Application can ensure this by programming the RTI1DIV field of the RCLKSRC register, if necessary • Is disabled via the CDDISx registers bit 6

2.4.2.1 Enabling / Disabling Clock Domains

Each clock domain can be independently enabled or disabled using the set of Clock Domain Disable registers – CDDIS, CDDISSET, and CDDISCLR.

Each bit in these registers corresponds to the clock domain number indicated in Table 2-10. For example, setting bit 1 in the CDDIS or CDDISSET registers disables the HCLK clock domain. The clock domain will be turned off only when every module that uses the HCLK domain gives the “permission” for HCLK to be turned off.

All clock domains are enabled by default, or upon a system reset, or whenever a wake up condition is detected.

2.4.2.2 Mapping Clock Sources to Clock Domains

Each clock domain needs to be mapped to a valid clock source. There are control registers that allow an application to choose the clock sources for each clock domain.

- ***Selecting clock source for GCLK1, HCLK, and VCLKx domains***

The CPU clock (GCLK1), the system module clock (HCLK), and the peripheral bus clocks (VCLKx) all use the same clock source. This clock source is selected via the GHVSRC register. The default source for the GCLK1, HCLK, and VCLKx is the main oscillator. That is, after power up, the GCLK1 and HCLK are running at the OSCIN frequency, while the VCLKx frequency is the OSCIN frequency divided by 2.

- ***Selecting clock source for VCLKA1 and VCLKA2 domains***

The clock source for VCLKA1 and VCLKA2 domains is selected via the VCLKASRC register. The default source for the VCLKA1 and VCLKA2 domains is the VCLK.

- ***Selecting clock source for VCLKA4 domain***

The clock source for VCLKA4 domain is selected via the VCLKACON1 register. The default source for the VCLKA4 domain is the VCLK.

- ***Selecting clock source for RTICLK1 domain***

The clock source for RTICLK1 domain is selected via the RCLKSRC register. The default source for the RTICLK1 domain is the VCLK.

NOTE: Selecting a clock source for RTICLK1 that is not VCLK

When the application chooses a clock source for RTICLK1 domain that is not VCLK, then the application must ensure that the resulting RTICLK1 frequency must be less than or equal to VCLK frequency divided by 3. The application can configure the RTI1DIV field of the RCLKSRC register for dividing the selected clock source frequency by 1, 2, 4 or 8 to meet this requirement.

Copyright © 2018, Texas Instruments Incorporated

2.4.3 Low Power Modes

All clock domains are active in the normal operating mode. This is the default mode of operation. As described in Section 2.4.1.1 and Section 2.4.2.1, the application can choose to disable any particular clock source and domain that it does not plan to use. Also, the peripheral central resource controller (PCR) has control registers to enable / disable the peripheral clock (VCLK) for each peripheral select. This offers the application a large number of choices for enabling / disabling clock sources, or clock domains, or clocks to specific peripherals.

This section describes three particular low-power modes and their typical characteristics. They are not the only low-power modes configurable by the application, as just described.

Table 2-11. Typical Low-Power Modes

Mode Name	Active Clock Source(s)	Active Clock Domain(s)	Wake Up Options	Suggested Wake Up Clock Source(s)	Wake Up Time(wake up detected -to- CPU code execution start)
Doze	Main oscillator	RTICLK1	RTI interrupt, GIO interrupt, CAN message, SCI message	Main oscillator	Flash pump sleep -> active transition time + Flash bank sleep -> standby transition time + Flash bank standby -> active transition time
Snooze	LF LPO	RTICLK1	RTI interrupt, GIO interrupt, CAN message, SCI message	HF LPO	HF LPO warm start-up time + Flash pump sleep -> active transition time + Flash bank sleep -> standby transition time + Flash bank standby -> active transition time
Sleep	None	None	GIO interrupt, CAN message, SCI message	HF LPO	HF LPO warm start-up time + Flash pump sleep -> active transition time + Flash bank sleep -> standby transition time + Flash bank standby -> active transition time

Copyright © 2018, Texas Instruments Incorporated

2.4.3.1 Typical Software Sequence to Enter a Low-Power Mode

1. Disable all non-CPU bus masters so they do not carry out any further bus transactions.
2. Program the flash banks and flash pump fall-back modes to be “sleep”.

   The flash pump transitions from active to sleep mode only after all the flash banks have switched from active to sleep mode.
3. Disable the clock sources that are not required to be kept active.

   A clock source does not get disabled until all clock domains using that clock source are disabled first, or are configured to use an alternate clock source.
4. Disable the clock domains that are not required to be kept active.

   A clock domain does not get disabled until all modules using that clock domain “give their permission” for that clock domain to be turned off.
5. Idle the Cortex-R5F core.

   The ARM Cortex-R5F CPU has internal power management logic, and requires a dedicated instruction to be used in order to enter a low power mode. This is the Wait For Interrupt (WFI) instruction.

   When a WFI instruction is executed, the Cortex-R5F core flushes its pipeline, flushes all write buffers, and completes all pending bus transactions. At this time the core indicates to the system that the clock to the core can be stopped. This indication is used by the Global Clock Module (GCM) to turn off the CPU clock domain (GCLK1) if the CDDIS register bit 0 is set.

2.4.3.2 Special Considerations for Entry to Low Power Modes

Some bus master modules – DMA, High-End Timer Transfer Units (HTUx), FlexRay Transfer Unit (FTU), and Parameter Overlay Module (POM), can have ongoing transactions when the application wants to enter a low power mode to turn off the clocks to those modules. This is not recommended as it could leave the device in an unpredictable state. Refer to the individual module user guides for more information about the sequence to be followed to safely enter a low-power mode.

2.4.3.3 Selecting Clock Source Upon Wake Up

The domains for CPU clock (GCLK1), the system clock (HCLK) and the peripheral clock (VCLKx) use the same clock source selected via the GHVSRC field of the GHVSRC register. The GHVSRC register also allows the application to choose the clock source after wake up via the GHVWAKE field.

When a wake up condition is detected, if the selected wake up clock source is not already active, the global clock module (GCM) will enable this selected clock source, wait for it to become valid, and then use it for the GCLK1, HCLK, and VCLKx domains. The other clock domains VCLKAx and RTICLK1 retain the configuration for their clock source selection registers – VCLKASRC, VCLKACON1 and RCLKSRC.

2.4.4 Clock Test Mode

The TMS570LC43x microcontrollers support a test mode which allows a user to bring out several different clock sources and clock domains on to the ECLK1 terminal in addition to outputting the external clock. This is very useful information for debug purposes. Each clock source also has a corresponding clock source valid status flag in the Clock Source Valid Status (CSVSTAT) register. The clock source valid status flags can also be brought out on to the N2HET1[12] terminal in this clock test mode.

The clock test mode is controlled by the CLKTEST register in the system module register frame (see Section 2.5.1.31).

The clock test mode is enabled by writing 0x5 to the CLK_TEST_EN field.

Copyright © 2018, Texas Instruments Incorporated

The signal to be brought out on to the ECLK1 terminal is defined by the SEL_ECP_PIN field, and the signal to be brought out on to the N2HET1[12] terminal is defined by the SEL_GIO_PIN field. The choices for these selections are defined in Table 2-12.

Table 2-12. Clock Test Mode Options

SEL_ECP_PIN	Signal on ECLK	SEL_GIO_PIN	Signal on N2HET1[12]
00000	Oscillator clock	0000	Oscillator Valid Status
00001	PLL1 clock output	0001	PLL1 Valid Status
00010	Reserved	0010	Reserved
00011	EXTCLKIN1	0011	Reserved
00100	Low-frequency LPO (Low-Power Oscillator) clock [CLK80K]	0100	Reserved
00101	High-frequency LPO (Low-Power Oscillator) clock [CLK10M]	0101	HF LPO Clock Output Valid Status [CLK10M]
00110	PLL2 clock output	0110	PLL2 Valid Status
00111	EXTCLKIN2	0111	Reserved
01000	GCLK1	1000	LF LPO Clock Output Valid Status [CLK80K]
01001	RTI1 Base	1001	Oscillator Valid Status

2.4.5 Embedded Trace Macrocell (ETM-R5)

The TMS570LC43x microcontrollers contain an ETM-R5 module with a 32-bit internal data port. The ETM-R5 module is connected to a Trace Port Interface Unit (TPIU) with a 32-bit data bus; the TPIU provides a 35-bit (32-bit data and 3-bit control) external interface for trace. The ETM-R5 is CoreSight compliant and follows the ETM v3 specification. For more details on the ETM-R5 specification, refer to the Embedded Trace Macrocell Architecture Specification.

The ETM clock source is selected as either VCLK or the external ETMTRACECLKIN pin. The selection is done by the EXTCTLOUT control bits of the TPIU EXTCTL_Out_Port register. The address of this register is TPIU base address + 0x404.

Before you begin accessing TPIU registers, the TPIU should be unlocked via the CoreSight key and 1h or 2h should be written to this register.

Figure 2-6. EXTCTL_Out_Port Register [offset = 404h]

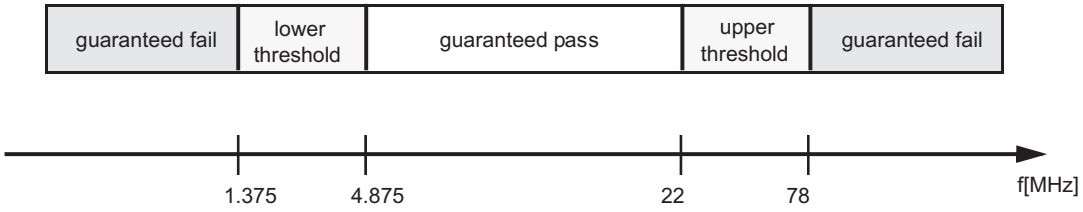
2.4.6 Safety Considerations for Clocks

The TMS570LC43x microcontrollers are targeted for use in several safety-critical applications. The following sections describe the internal or external monitoring mechanisms that detect and signal clock source failures.

Copyright © 2018, Texas Instruments Incorporated

2.4.6.1 Oscillator Monitor



The oscillator clock frequency is monitored by a dedicated circuitry called CLKDET using the HF LPO as the reference clock. The CLKDET flags an oscillator fail condition whenever the OSCIN frequency falls outside of a range which is defined by the HF LPO frequency.

The valid OSCIN range is defined as a minimum of $f_{(HF\ LPO)}$ / 4 to a maximum of $f_{(HF\ LPO)}$ × 4.

The untrimmed HF LPO frequency on this device can range from 5.5 MHz to 19.5 MHz. This results in a valid OSCIN frequency range depicted in Figure 2-7.

The application can select the device response to an oscillator fail indication. Refer to Chapter 14 for more details on the oscillator monitoring and the system response choices.

Figure 2-7. LPO and Clock Detection, Untrimmed HF LPO

2.4.6.2 PLL Slip Detector

Both the PLL macros implemented on the microcontrollers have an embedded slip detection circuit. A PLL slip is detected by the slip detector under the following conditions:

1. Reference cycle slip, RFSLIP — the output clock is running *too fast* relative to the reference clock
2. Feedback cycle slip, FBSLIP — the output clock is running *too slow* relative to the reference clock

The device also includes optional filters that can be enabled before a slip indication from the PLL is actually logged in the system module Global Status Register (GLBSTAT). Also, once a PLL slip condition is logged in the system module global status register, the application can choose the device's response to the slip indication. Refer to Chapter 14 for more details on PLL slip and the system response choices.

2.4.6.3 External Clock Monitor

The microcontrollers support two terminals called ECLK1 and ECLK2 – External Clock, which are used to output a slow frequency which is divided down from the device system clock frequency. An external circuit can monitor the ECLK1 and/or ECLK2 frequency in order to check that the device is operating at the correct frequency.

The frequency of the signal output on the ECLKx pin can be divided down by 1 to 65536 from the peripheral clock (VCLK) frequency using the External Clock Prescaler Control Register (ECPCNTL) for ECLK1 and ECPCNTL1 for ECLK2. The actual clock output on ECLK1 is enabled by setting the ECP CLK FUN bit of the SYSPC1 control register. By default, the ECLK1 terminal is in GIO mode. ECLK2 functionality can be enabled by writing 5h to the ECP_KEY field of the ECPCNTL1 register.

NOTE: ECLK2 is multiplexed with EMIF_CLK and ECLK2 is not a primary function after reset. User will need to select ECLK2 to be brought out to the terminal using IOMM module.

2.4.6.4 Dual-Clock Comparators

The microcontrollers include two instances of the dual-clock comparator (DCC) module. This module includes two down counters which independently count from two separate seed values at the rate of two independent clock frequencies. One of the clock inputs is a reference clock input, selectable between the main oscillator or the HF LPO in functional mode. The second clock input is selectable from among a set of defined signals as described in Section 2.4.6.4.1 and Section 2.4.6.4.2. This mechanism can be used to use a known-good clock to measure the frequency of another clock.

Copyright © 2018, Texas Instruments Incorporated

2.4.6.4.1 DCC1

As can be seen, the main oscillator (OSCIN) can be used for counter 0 as a “known-good” reference clock. The clock for counter 1 can be selected from among 8 options. Refer to the DCC module chapter for more details on the DCC usage.

Table 2-14. DCC1 Counter 0 Clock Inputs

Clock Source [3–0]	Clock / Signal Name
All other values	oscillator (OSCIN)
5h	HF LPO
Ah	test clock (TCK)

Table 2-15. DCC1 Counter 1 Clock / Signal Inputs

Key [3–0]	Clock Source [3–0]	Clock / Signal Name
Ah	0h	PLL1 free-running clock output
	1h	PLL2 free-running clock output
	2h	LF LPO

2.4.6.4.2 DCC2

As can be seen, the main oscillator (OSCIN) can be used for counter 0 as a “known-good” reference clock. The clock for counter 1 can be selected from among 2 options. Refer to the DCC module chapter for more details on the DCC usage.

Table 2-16. DCC2 Counter 0 Clock Inputs

2.5 System and Peripheral Control Registers

The following sections describe the system and peripheral control registers of the TMS570LC43x microcontroller.

2.5.1 Primary System Control Registers (SYS)

This section describes the SYSTEM registers. These registers are divided into two separate frames. The start address of the primary system module frame is FFFF FF00h. The start address of the secondary system module frame is FFFF E100h. The registers support 8-, 16-, and 32-bit writes. The offset is relative to the system module frame start address.

Table 2-18 contains a list of the primary system control registers.

Table 2-18. Primary System Control Registers

Offset	Acronym	Register Description	Section

Table 2-19. SYS Pin Control Register 1 (SYSPC1) Field Descriptions

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	ECPCLKFUN		ECLK function. This bit changes the function of the ECLK pin.
		0	ECLK is in GIO mode.
		1	ECLK is in functional mode as a clock output.
			Note: Proper ECLK duty cycle is not guaranteed until 1 ECLK cycle has elapsed after switching into functional mode.

2.5.1.2 SYS Pin Control Register 2 (SYSPC2)

The SYSPC2 register, shown in Figure 2-9 and described in Table 2-20, controls whether the pin is an input or an output when in GIO mode.

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	ECPCLKDIR		ECLK data direction. This bit controls the direction of the ECLK pin when it is configured to be in GIO mode only.
		0	The ECLK pin is an input.
			Note: If the pin direction is set as an input, the output buffer is tristated.
		1	The ECLK pin is an output.
			Note: The ECLK pin is placed into GIO mode by clearing the ECPCLKFUN bit to 0 in the SYSPC1 register.

0	ECPCLKDIN		ECLK data in. This bit displays the logic state of the ECLK pin when it is configured to be in GIO mode.
		0	The ECLK pin is at logic low (0).
		1	The ECLK pin is at logic high (1).

2.5.1.4 SYS Pin Control Register 4 (SYSPC4)

The SYSPC4 register, shown in Figure 2-11 and described in Table 2-22, controls the logic level output function of the ECLK pin when it is configured as an output in GIO mode.

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	ECPCLKDOUT		ECLK data out write. This bit is only active when the ECLK pin is configured to be in GIO mode. Writes to this bit will only take effect when the ECLK pin is configured as an output in GIO mode. The current logic state of the ECLK pin will be displayed by this bit in both input and output GIO mode.
		0	The ECLK pin is driven to logic low (0).
		1	The ECLK pin is driven to logic high (1).
			Note: The ECLK pin is placed into GIO mode by clearing the ECPCLKFUN bit to 0 in the SYSPC1 register. The ECLK pin is placed in output mode by setting the ECPCLKDIR bit to 1 in the SYSPC2 register.

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	ECPCLKSET		ECLK data out set. This bit drives the output of the ECLK pin high when set in GIO output mode.
		0	*Write:* Writing a 0 has no effect.
		1	*Write:* The ECLK pin is driven to logic high (1).
			Note: The current logic state of the ECPCLKDOUT bit will also be displayed by this bit when the pin is configured in GIO output mode.
			Note: The ECLK pin is placed into GIO mode by clearing the ECPCLKFUN bit to 0 in the SYSPC1 register. The ECLK pin is placed in output mode by setting the ECPCLKDIR bit to 1 in the SYSPC2 register.

2.5.1.6 SYS Pin Control Register 6 (SYSPC6)

The SYSPC6 register, shown in Figure 2-13 and described in Table 2-24, controls the clear function of the ECLK pin when it is configured as an output in GIO mode..

Table 2-25. SYS Pin Control Register 7 (SYSPC7) Field Descriptions

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	ECPCLKODE		ECLK open drain enable. This bit is only active when ECLK is configured to be in GIO mode.
		0	The ECLK pin is configured in push/pull (normal GIO) mode.
		1	The ECLK pin is configured in open drain mode. The ECPCLKDOUT bit in the SYSPC4 register controls the state of the ECLK output buffer:
			ECPCLKDOUT = 0: The ECLK output buffer is driven low.
			ECPCLKDOUT = 1: The ECLK output buffer is tristated.
			Note: The ECLK pin is placed into GIO mode by clearing the ECPCLKFUN bit to 0 in the SYSPC1 register.

2.5.1.8 SYS Pin Control Register 8 (SYSPC8)

The SYSPC8 register, shown in Figure 2-15 and described in Table 2-26, controls the pull enable function of the ECLK pin when it is configured as an input in GIO mode.

Figure 2-15. SYS Pin Control Register 8 (SYSPC8) (offset = 1Ch)

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	ECPCLKPUE		ECLK pull enable. Writes to this bit will only take effect when the ECLK pin is configured as an input in GIO mode.
		0	ECLK pull enable is active.
		1	ECLK pull enable is inactive.
			Note: The pull direction (up/down) is selected by the ECPCLKPS bit in the SYSPC9 register.
			Note: The ECLK pin is placed into GIO mode by clearing the ECPCLKFUN bit to 0 in the SYSPC1 register. The ECLK pin is placed in input mode by clearing the ECPCLKDIR bit to 0 in the SYSPC2 register.

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	ECPCLKPS		ECLK pull up/pull down select. This bit is only active when ECLK is configured as an input in GIO mode and the pull up/pull down logic is enabled.
		0	ECLK pull down is selected, when pull up/pull down logic is enabled.
		1	ECLK pull up is selected, when pull up/pull down logic is enabled.
			Note: The ECLK pin pull up/pull down logic is enabled by clearing the ECPCLKPUE bit to 0 in the SYSPC8 register.
			Note: The ECLK pin is placed into GIO mode by clearing the ECPCLKFUN bit to 0 in the SYSPC1 register. The ECLK pin is placed in input mode by clearing the ECPCLKDIR bit to 0 in the SYSPC2 register.

2.5.1.13 Clock Domain Disable Register (CDDIS)

The CDDIS register, shown in Figure 2-20 and described in Table 2-32, controls the state of the clock domains.

NOTE: All the clock domains are enabled on wakeup.

The application should assure that when HCLK and VCLK_sys are turned off through the HCLKOFF bit, the GCLK1 domain is also turned off.

The register bits in CDDIS are designated as high-integrity bits and have been implemented with error-correcting logic such that each bit, although read and written as a single bit, is actually a multi-bit key with error correction capability. As such, single-bit flips within the “key” can be corrected allowing protection of the system as a whole. An error detected is signaled to the ESM module.

2.5.1.18 RTI Clock Source Register (RCLKSRC)

The RCLKSRC register, shown in Figure 2-25 and described in Table 2-37, controls the RTI (Real Time Interrupt) clock source selection.

NOTE: Important constraint when the RTI clock source is not VCLK

If the RTIx clock source is chosen to be anything other than the default VCLK, then the RTI clock needs to be at least three times slower than the VCLK. This can be achieved by configuring the RTIxCLK divider in this register. This divider is internally bypassed when the RTIx clock source is VCLK.

Figure 2-25. RTI Clock Source Register (RCLKSRC) (offset = 50h)

Reserved		ROM_DIV		Reserved		MSTGENA	
R-0		R/WP-0		R-0		R/WP-5h	

LEGEND: R = Read only; R/W = Read/Write; WP = Write in privileged mode only; -*n* = value after reset

Table 2-39. Memory Self-Test Global Control Register (MSTGCR) Field Descriptions

Bit	Field	Value	Description
31-24	Reserved	0	Reads return 0. Writes have no effect.
23-16	Reserved	0-1	Reads return 0 or 1 and depends on what is written in privileged mode. The functionality of these bits are unavailable in this device.
15-10	Reserved	0	Reads return 0. Writes have no effect.
9-8	ROM_DIV		Prescaler divider bits for ROM clock source.
		0	ROM clock source is GCLK1 divided by 1. PBIST will reset for 16 VBUS cycles.
		1h	ROM clock source is GCLK1 divided by 2. PBIST will reset for 32 VBUS cycles.
		2h	ROM clock source is GCLK1 divided by 4. PBIST will reset for 64 VBUS cycles.
		3h	ROM clock source is GCLK1 divided by 8. PBIST will reset for 96 VBUS cycles.
7-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	MSTGENA		Memory self-test controller global enable key
			Note: Enabling the MSTGENA key will generate a reset to the state machine of the selected PBIST controller.
		Ah	Memory self-test controller is enabled.
		Others	Memory self-test controller is disabled.
			Note: It is recommended that a value of Ah be used to disable the memory self-test controller. This value will give maximum protection from a bit flip inducing event that would inadvertently enable the controller.

2.5.1.22 MBIST Controller/ Memory Initialization Enable Register (MSINENA)

The MSINENA register, shown in Figure 2-29 and described in Table 2-41, enables PBIST controllers for memory self test and the memory modules initialized during automatic hardware memory initialization.

Figure 2-29. MBIST Controller/Memory Initialization Enable Register (MSINENA) (offset = 60h)

31	16
MSIENA	
R/WP-0	

15	0
MSIENA	
R/WP-0	

LEGEND: R/W = Read/Write; WP = Write in privileged mode only; -*n* = value after reset

Table 2-41. MBIST Controller/Memory Initialization Enable Register (MSINENA) Field Descriptions

Bit	Field	Value	Description
31-0	MSIENA		PBIST controller and memory initialization enable register. In memory self-test mode, all the corresponding bits of the memories to be tested should be set before enabling the global memory self-test controller key (MSTGENA) in the MSTGCR register (offset 58h). The reason for this is that MSTGENA, in addition to being the global enable for all individual PBIST controllers, is the source for the reset generation to all the PBIST controller state machines. Disabling the MSTGENA or MINITGENA key (by writing from an Ah to any other value) will reset all the MSIENA[31-0] bits to their default values.
		0	*In memory self-test mode (MSTGENA = Ah):* PBIST controller [31-0] is disabled. *In memory Initialization mode (MINITGENA = Ah):* Memory module [31-0] auto hardware initialization is disabled.
		1	*In memory self-test mode (MSTGENA = Ah):* PBIST controller [31-0] is enabled. *In memory Initialization mode (MINITGENA = Ah):* Memory module [31-0] auto hardware initialization is enabled. **Note: Software should ensure that both the memory self-test global enable key (MSTGENA) and the memory hardware initialization global key (MINITGENA) are not enabled at the same time.**

		1	*Read:* Memory module[31-0] hardware initialization is completed. *Write:* The bit is cleared to 0. **Note: Disabling the MINITGENA key (by writing from a Ah to any other value) will reset all the individual status bits to 0.**

2.5.1.25 PLL Control Register 1 (PLLCTL1)

The PLLCTL1 register, shown in Figure 2-32 and described in Table 2-44, controls the output frequency of PLL1 (Clock Source 1 - FMzPLL). It also controls the behavior of the device if a PLL slip or oscillator failure is detected.

Figure 2-32. PLL Control Register 1 (PLLCTL1) (offset = 70h)

31	30	29	28	24
ROS	BPOS		PLLDIV

Table 2-44. PLL Control Register 1 (PLLCTL1) Field Descriptions

Bit	Field	Value	Description
31	ROS		Reset on PLL Slip.
		0	Do not reset system when PLL slip is detected.
		1	Reset when PLL slip is detected.
			Note: BPOS (Bits 30-29) must also be enabled for ROS to be enabled.
30-29	BPOS		Bypass of PLL Slip.
		2h	Bypass on PLL Slip is disabled. If a PLL Slip is detected no action is taken.
		Others	Bypass on PLL Slip is enabled. If a PLL Slip is detected the device will automatically bypass the PLL and use the oscillator to provide the device clock.
			Note: If ROS (Bit 31) is set to 1, the device will be reset if a PLL Slip and the PLL will be bypassed after the reset occurs.
28-24	PLLDIV		PLL Output Clock Divider
			R = PLLDIV + 1 $f_{PLL\ CLK} = f_{post\_ODCLK} / R$
		0	$f_{PLL\ CLK} = f_{post\text{-}ODCLK} / 1$
		1h	$f_{PLL\ CLK} = f_{post\text{-}ODCLK} / 2$
		:	:
		1Fh	$f_{PLL\ CLK} = f_{post\text{-}ODCLK} / 32$
23	ROF		Reset on Oscillator Fail.
		0	Do not reset system when oscillator is out of range.
		1	The ROF bit enables the OSC_FAIL condition to generate a system reset. If the ROF bit in the PLLCTL1 register is set when the oscillator fails, then a system reset occurs.
22	Reserved	0	Value has no effect on PLL operation.
21-16	REFCLKDIV		Reference Clock Divider
			NR = REFCLKDIV + 1 $f_{INT\ CLK} = f_{OSCIN} / NR$
		0	$f_{INT\ CLK} = f_{OSCIN} / 1$
		1h	$f_{INT\ CLK} = f_{OSCIN} / 2$
		:	:
		3Fh	$f_{INT\ CLK} = f_{OSCIN} / 64$
15-0	PLLMUL		PLL Multiplication Factor
			NF = (PLLMUL / 256) + 1, valid multiplication factors are from 1 to 256. $f_{VCO\ CLK} = f_{INT\ CLK} \times NF$
		0h	$f_{VCO\ CLK} = f_{INT\ CLK} \times 1$
		100h	$f_{VCO\ CLK} = f_{INT\ CLK} \times 2$
		:	:
		5B00h	$f_{VCO\ CLK} = f_{INT\ CLK} \times 92$
		5C00h	$f_{VCO\ CLK} = f_{INT\ CLK} \times 93$
		:	:
		FF00h	$f_{VCO\ CLK} = f_{INT\ CLK} \times 256$

2.5.1.26 PLL Control Register 2 (PLLCTL2)

The PLLCTL2 register, shown in Figure 2-33 and described in Table 2-45, controls the modulation characteristics and the output divider of the PLL.

Figure 2-33. PLL Control Register 2 (PLLCTL2) (offset = 74h)

31	30	22	21	20	16
FMENA	SPREADINGRATE		Rsvd	MULMOD	
R/WP-0	R/WP-1FFh		R-0	R/WP-0	

15	12	11	9	8	0
MULMOD		ODPLL		SPR_AMOUNT	
R/WP-7h		R/WP-0		R/WP-0	

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 2-45. PLL Control Register 2 (PLLCTL2) Field Descriptions

Bit	Field	Value	Description
31	FMENA		Frequency Modulation Enable.
		0	Disable frequency modulation.
		1	Enable frequency modulation.
30-22	SPREADINGRATE		NS = SPREADINGRATE + 1 $f_{mod} = f_s = f_{INT\ CLK}/(2 \times NS)$
		0	$f_{mod} = f_s = f_{INT\ CLK} / (2 \times 1)$
		1h	$f_{mod} = f_s = f_{INT\ CLK} / (2 \times 2)$
		:	:
		1FFh	$f_{mod} = f_s = f_{INT\ CLK} / (2 \times 512)$
21	Reserved	0	Value has no effect on PLL operation.
20-12	MULMOD		Multiplier Correction when Frequency Modulation is enabled. When FMENA = 0, MUL_when_MOD = 0; when FMENA = 1, MUL_when_MOD = (MULMOD / 256)
		0	No adder to NF.
		8h	MUL_when_MOD = 8/256
		9h	MUL_when_MOD = 9/256
		:	:
		1FFh	MUL_when_MOD = 511/256
11-9	ODPLL		Internal PLL Output Divider OD = ODPLL + 1 $f_{post\text{-}ODCLK} = f_{VCO\ CLK}/OD$ **Note: PLL output clock is gated off, if ODPLL is changed while the PLL is active.**
		0	$f_{post\text{-}ODCLK} = f_{VCO\ CLK} / 1$
		1h	$f_{post\text{-}ODCLK} = f_{VCO\ CLK} / 2$
		:	:
		7h	$f_{post\text{-}ODCLK} = f_{VCO\ CLK} / 8$
8-0	SPR_AMOUNT		Spreading Amount NV = (SPR_AMOUNT + 1)/2048 NV ranges from 1/2048 to 512/2048 Note that the PLL output clock is disabled for 1 modulation period, if the SPR_AMOUNT field is changed while the frequency modulation is enabled. If frequency modulation is disabled and SPR_AMOUNT is changed, there is no effect on the PLL output clock.
		0	NV = 1/2048
		1h	NV = 2/2048
		:	:
		1FFh	NV = 512/2048

2.5.1.31 Clock Test Register (CLKTEST)

The CLKTEST register, shown in Figure 2-38 and described in Table 2-50, controls the clock signal that is supplied to the ECLK pin for test and debug purposes.

NOTE: Clock Test Register Usage

This register should only be used for test and debug purposes.

Figure 2-38. Clock Test Register (CLKTEST) (offset = 8Ch)

31–27	26	25	24
Reserved	TEST	RANGEDET CTRL	RANGEDET ENASSEL
R-0	R/WP-0	R/WP-0	R/WP-0

23–20	19–16
Reserved	CLK_TEST_EN
R-0	R/WP-Ah

15–12	11–8	7–5	4–0
Reserved	SEL_GIO_PIN	Reserved	SEL_ECP_PIN
R-0	R/WP-0	R-0	R/WP-0

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 2-50. Clock Test Register (CLKTEST) Field Descriptions

Bit	Field	Value	Description
31-27	Reserved	0	Reads return 0. Writes have no effect.
26	TEST	0	This bit is used for test purposes. It must be written to 0.
25	RANGEDETCTRL		Range detection control. This bit's functionality is dependant on the state of the RANGEDETENSSEL bit (Bit 24) of the CLKTEST register.
		0	The clock monitor range detection circuitry (RANGEDETECTENABLE) is disabled.
		1	The clock monitor range detection circuitry (RANGEDETECTENABLE) is enabled.
24	RANGEDETENASSEL		Selects range detection enable. This bit resets asynchronously on power on reset.
		0	The range detect enable is generated by the hardware in the clock monitor wrapper.
		1	The range detect enable is controlled by the RANGEDETCTRL bit (Bit 25) of the CLKTEST register.
23-20	Reserved	0	Reads return 0. Writes have no effect.
19-16	CLK_TEST_EN		Clock test enable. This bit enables the clock going to the ECLK pin. This bit field enables or disables clock going to device pins. Two pins in a device can get clock sources by enabling CLK_TEST_EN bits. One pin is the ECP and second pin is a device specific GIO pin. These bits need to asynchronously reset.
			Note: The ECLK pin must also be placed into Functional mode by setting the ECPCLKFUN bit to 1 in the SYSPC1 register.
		5h	Clock going to ECLK pin is enabled.
		Others	Clock going to ECLK pin is disabled.
15-12	Reserved	0	Reads return 0. Writes have no effect.

Reserved	
R/WP-0	

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 2-53. General Purpose Register (GPREG1) Field Descriptions

Bit	Field	Value	Description
31-26	Reserved	0	Reads return 0. Writes have no effect.
25-20	PLL1_FBSLIP_FILTER_COUNT		FBSLIP down counter programmed value. Configures the system response when a FBSLIP is indicated by the PLL macro. When PLL1_FBSLIP_FILTER_KEY is not Ah, the down counter counts from the programmed value on every LPO high-frequency clock once PLL macro indicates FBSLIP. When the count reaches 0, if the synchronized FBSLIP signal is still high, an FBSLIP condition is indicated to the system module and is captured in the global status register. When the FBSLIP signal from the PLL macro is de-asserted before the count reaches 0, the counter is reloaded with the programmed value. On reset, counter value is 0. Counter must be programmed to a non-zero value and enabled for the filtering to be enabled.
		0	Filtering is disabled.
		1h	Filtering is enabled. Every slip is recognized.
		2h	Filtering is enabled. The slip must be at least 2 HF LPO cycles wide in order to be recognized as a slip.
		:	:
		3Fh	Filtering is enabled. The slip must be at least 63 HF LPO cycles wide in order to be recognized as a slip.
19-16	PLL1_FBSLIP_FILTER_KEY		Enable the FBSLIP filtering.
		5h	On reset, the FBSLIP filter is disabled and the FBSLIP passes through.
		Fh	This is an unsupported value. You should avoid writing this value to this bit field.
		All other values	FBSLIP filtering is enabled. Recommended to program Ah in this bit field. Enabling of the FBSLIP occurs when the KEY is programmed and a non-zero value is present in the COUNT field.
15-0	Reserved	0-1	Reads return 0 or 1 and write in privilege mode. The functionality of this bit is unavailable in this device.

Reserved	
R-0	

15	8	7	0
SSKEY1		SSDATA1	
R/W-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 2-54. System Software Interrupt Request 1 Register (SSIR1) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
15-8	SSKEY1	0-FFh	System software interrupt request key. A 075h written to these bits initiates IRQ/FIQ interrupts. Data in this field is always read as 0. The SSKEY1 field can be written into only if the write data matches the key (75h). The SSDATA1 field can only be written into if the write data into this field, the SSKEY1 field, matches the key (75h).
7-0	SSDATA1	0-FFh	System software interrupt data. These bits contain user read/write register bits. They may be used by the application software as different entry points for the interrupt routine. The SSDATA1 field cannot be written into unless the write data into the SSKEY1 field matches the key (75h); therefore, byte writes cannot be performed on the SSDATA1 field.

NOTE: This register is mirrored at offset FCh for compatibility reasons.

2.5.1.41 CPU Reset Control Register (CPURSTCR)

The CPURSTCR register shown in Figure 2-48 and described in Table 2-60 allows a reset to the Cortex-R5F CPU to be generated.

NOTE: The register bits in CPURSTCR are designated as high-integrity bits and have been implemented with error-correcting logic such that each bit, although read and written as a single bit, is actually a multi-bit key with error correction capability. As such, single-bit flips within the “key” can be corrected allowing protection of the system as a whole. An error detected is signaled to the ESM module.

2.5.1.42 Clock Control Register (CLKCNTL)

The CLKCNTL register, shown in Figure 2-49 and described in Table 2-61, controls peripheral reset and the peripheral clock divide ratios.

NOTE: VCLK and VCLK2 clock ratio restrictions.

The VCLK2 frequency must always be greater than or equal to the VCLK frequency. The VCLK2 frequency must be an integer multiple of the VCLK frequency.

In addition, the VCLK and VCLK2 clock ratios must not be changed simultaneously. When increasing the frequency (decreasing the divider), first change the VCLK2R field and then change the VCLKR field. When reducing the frequency (increasing the divider), first change the VCLKR field and then change the VCLK2R field.

You should do a read-back between the two writes. This assures that there are enough clock cycles between the two writes.

Figure 2-49. Clock Control Register (CLKCNTL) (offset = D0h)

2.5.1.43 ECP Control Register (ECPCNTL)

The ECP register, shown in Figure 2-50 and described in Table 2-62, configures the ECLK pin in functional mode.

NOTE: ECLK Functional mode configuration.

The ECLK pin must be placed into Functional mode by setting the ECPCLKFUN bit to 1 in the SYSPC1 register before a clock source will be visible on the ECLK pin.

Figure 2-50. ECP Control Register (ECPCNTL) (offset = D4h)

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 2-62. ECP Control Register (ECPCNTL) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24	ECPSSEL		This bit allows the selection between VCLK and OSCIN as the clock source for ECLK. **Note: Other ECLK clock sources are available for debug purposes by configuring the CLKTEST register.**
		0	VCLK is selected as the ECP clock source.
		1	OSCIN is selected as the ECP clock source.
23	ECPCOS		ECP continue on suspend. **Note: Suspend mode is entered while performing certain JTAG debugging operations.**
		0	ECLK output is disabled in suspend mode. ECLK output will be shut off and will not be seen on the I/O pin of the device.
		1	ECLK output is not disabled in suspend mode. ECLK output will not be shut off and will be seen on the I/O pin of the device.
22-18	Reserved	0	Reads return 0. Writes have no effect.
17-16	Reserved	0	Reads return 0 or 1 depends on what is written. The functionality of this bit is unavailable in this device.
15-0	ECPDIV	0-FFFFh	ECP divider value. The value of ECPDIV bits determine the external clock (ECP clock) frequency as a ratio of VBUS clock or OSCIN as shown in the formula: $ECLK = \frac{VCLK\,or\,OSCIN}{(ECPDIV + 1)}$

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 2-63. DEV Parity Control Register 1 (DEVCR1) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	DEVPARSEL		Device parity select bit key.
			Note: After an odd (DEVPARSEL = Ah) or even (DEVPARSEL = 5h) scheme is programmed into the DEVPARSEL register, any one bit change can be detected and will retain its programmed scheme. More than one bit changes in DEVPARSEL will cause a default to odd parity scheme.
		5h	The device parity is even.
		Ah	The device parity is odd.

2.5.1.45 System Exception Control Register (SYSECR)

The SYSECR register, shown in Figure 2-52 and described in Table 2-64, is used to generate a software reset.

NOTE: The register bits in SYSECR are designated as high-integrity bits and have been implemented with error-correcting logic such that each bit, although read and written as a single bit, is actually a multi-bit key with error correction capability. As such, single-bit flips within the “key” can be corrected allowing protection of the system as a whole. An error detected is signaled to the ESM module.

2.5.1.46 System Exception Status Register (SYSESR)

The SYSESR register, shown in Figure 2-53 and described in Table 2-65, shows the source for different resets encountered. Previous reset source status bits are not automatically cleared if new resets occur. After reading this register, the software should clear any flags that are set so that the source of future resets can be determined. Any bit in this register can be cleared by writing a 1 to the bit.

Figure 2-53. System Exception Status Register (SYSESR) (offset = E4h)

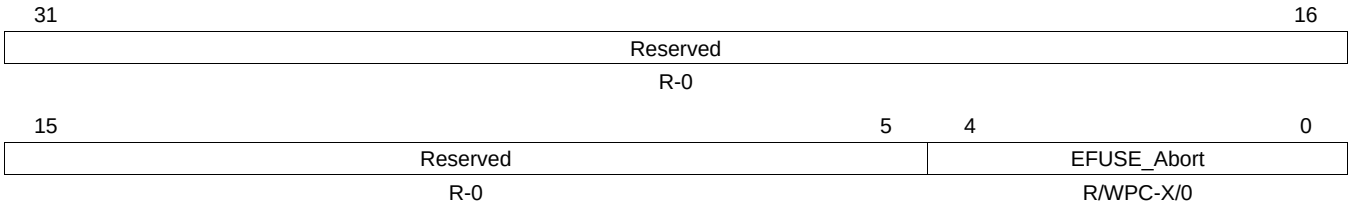
LEGEND: R/W = Read/Write; R = Read only; C = Clear; X = value is unchanged after reset; X* = 0 after PORST but unchanged after other resets; *-n* = value after reset

Table 2-65. System Exception Status Register (SYSESR) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
15	PORST		Power-on reset. This bit is set when a power-on reset occurs, either internally asserted by the VMON or externally asserted by the nPORRST pin.
		0	No power-on reset has occurred since this bit was last cleared.
		1	A reset was caused by a power-on reset. (This bit should be cleared after being read so that subsequent resets can be properly identified as not being power-on resets.)
14	OSCRST		Reset caused by an oscillator failure or PLL cycle slip. This bit is set when a reset is caused by an oscillator failure or PLL slip. Write 1 will clear this bit. Write 0 has no effect.
			Note: The action taken when an oscillator failure or PLL slip is detected must configured in the PLLCTL1 register.
		0	No reset has occurred due to an oscillator failure or a PLL cycle slip.
		1	A reset was caused by an oscillator failure or a PLL cycle slip.
13	WDRST		Watchdog reset flag. This bit is set when the last reset was caused by the digital watchdog (DWD). Write 1 will clear this bit. Write 0 has no effect.
		0	No reset has occurred because of the DWD.
		1	A reset was caused by the DWD.
12	Reserved	0	Reads return 0. Writes have no effect.
11	DBGRST		Debug reset flag. This bit is set when the last reset was caused by the debugger reset request. Write 1 will clear this bit. Write 0 has no effect.
		0	No reset has occurred because of the debugger.
		1	A reset was caused by the debugger.
10-8	Reserved	0	Reads return 0. Writes have no effect.
7	ICSTRST		Interconnect reset flag. This bit is set when the last CPU reset was caused by the entering and exiting of interconnect self-test check. While the interconnect is under self-test check, the CPU is also held in reset until the interconnect self-test is complete.
		0	No CPUx reset has occurred because of an interconnect self-test check.
		1	A reset has occurred to the CPUx because of the interconnect self-test check.
6	Reserved	0	Reads return 0. Writes have no effect.

Copyright © 2018, Texas Instruments Incorporated

Table 2-65. System Exception Status Register (SYSESR) Field Descriptions (continued)



Bit	Field	Value	Description
5	CPURST		CPU reset flag. This bit is set when the CPU is reset. Write 1 will clear this bit. Write 0 has no effect.
			Note: A CPU reset can be initiated by the CPU self-test controller (LBIST) or by toggling the CPU RESET bit field in CPURSTCR register.
		0	No CPU reset has occurred.
		1	A CPU reset occurred.
4	SWRST		Software reset flag. This bit is set when a software system reset has occurred. Write 1 will clear this bit. Write 0 has no effect.
			Note: A software system reset can be initiated by writing to the RESET bits in the SYSECR register.
		0	No software reset has occurred.
		1	A software reset occurred.
3	EXTRST		External reset flag. This bit is set when a reset is caused by the external reset pin nRST or by any reset that also asserts the nRST pin (PORST, OSCRST, WDRST, WD2RST, and SWRST).
		0	The external reset pin has not asserted a reset.
		1	A reset has been caused by the external reset pin.
2-0	Reserved	0	Reads return 0. Writes have no effect.

2.5.1.47 System Test Abort Status Register (SYSTASR)

This register is shown in Figure 2-54 and described in Table 2-66.

Figure 2-54. System Test Abort Status Register (SYSTASR) (offset = E8h)

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; C = Clear; -X = value is unchanged after reset; -*n* = value after reset

Table 2-66. System Test Abort Status Register (SYSTASR) Field Descriptions

Bit	Field	Value	Description
31-5	Reserved	0	Reads return 0. Writes have no effect.
4-0	EFUSE_Abort		Test Abort status flag. These bits are set when test abort occurred:
		0	*Read:* The last operation (if any) completed successfully. This is also the value that the error/status register is set to after reset.
		1h	*Read:* Controller times out because there is no last row sent from the FuseROM.
		2h	*Read:* The autoload machine was started, either through the SYS_INITZ signal from the system or the JTAG data register. In either case, the autoload machine did not find enough FuseROM data to fill the scan chain.
		3h	*Read:* The autoload machine was started, either through the SYS_INITZ signal from the system or the JTAG data register. In either case, the autoload machine starts the scan chain with a signature it expects to see after the scan chain is full. The autoload machine was able to fill the scan chain, but the wrong signature was returned.
		4h	*Read:* The autoload machine was started, either through the SYS_INITZ signal from the system or the JTAG data register. In either case, the autoload machine was not able or not allowed to complete its operation.
		Others	*Read:* Reserved.
		1Fh	*Write:* These bits are cleared to 0.

LEGEND: R = Read only; K =Constant value; *-n* = value after reset

Table 2-68. Device Identification Register (DEVID) Field Descriptions

Bit	Field	Value	Description
31	CP15		CP15 CPU. This bit indicates whether the CPU has a coprocessor 15 (CP15).
		0	The CPU has no CP15 present.
		1	The CPU has a CP15 present. The CPU ID can be read using the CP15 C0,C0,0 register.
30-17	UNIQUE ID	0-3FFFh	Device ID. The device ID is unique by device configuration.
16-13	TECH		These bits define the process technology by which the device was manufactured.
		0	Device manufactured in the C05 process technology.
		1h	Device manufactured in the F05 process technology.
		2h	Device manufactured in the C035 process technology.
		3h	Device manufactured in the F035 process technology.
		4h	Device manufactured in the C021 process technology.
		5h	Device manufactured in the F021 process technology.
		6h-7h	Reserved
12	I/O VOLTAGE		Input/output voltage. This bit defines the I/O voltage of the device.
		0	The I/O voltage is 3.3 V.
		1	The I/O voltage is 5 V.
11	PERIPHERAL PARITY		Peripheral parity. This bit indicates whether or not peripheral memory parity is present.
		0	The peripheral memories have no parity.
		1	The peripheral memories have parity.
10-9	FLASH ECC		These bits indicate which parity is present for the program memory.
		0	No memory protection is present.
		1h	The program memory (Flash) has single-bit parity.
		2h	The program memory (Flash) has ECC.
		3h	This combination is reserved.
8	RAM ECC		RAM ECC. This bit indicates whether or not RAM memory ECC is present.
		0	The RAM memories do not have ECC.
		1	The RAM memories have ECC.
7-3	VERSION	0-1Fh	Version. These bits provide the revision of the device.
2-0	PLATFORM ID	5h	The device is part of the TMS570Px family. The TMS570Px ID is always 5h.

2.5.1.50 Software Interrupt Vector Register (SSIVEC)

The SSIVEC register, shown in Figure 2-57 and described in Table 2-69, contains information about software interrupts.

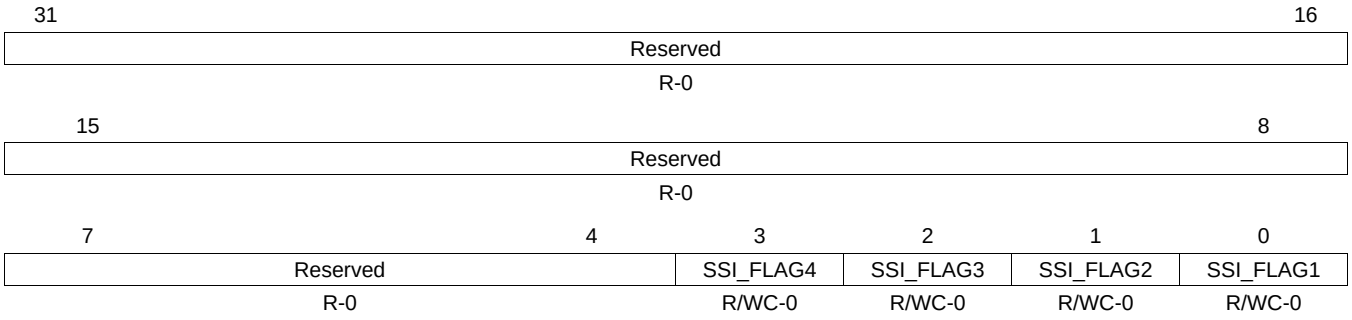
Figure 2-57. Software Interrupt Vector Register (SSIVEC) (offset = F4h)

31	16
Reserved	
R-0	

15	8	7	0
SSIDATA		SSIVECT	
R-0		R-0	

LEGEND: R = Read only; -*n* = value after reset

Table 2-69. Software Interrupt Vector Register (SSIVEC) Field Descriptions



Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
15-8	SSIDATA	0-FFh	System software interrupt data key. These bits contain the data key value of the source for the system software interrupt, which is indicated by the vector in the SSIVEC[7-0] field.
7-0	SSIVECT		These bits contain the source for the system software interrupt. **Note: A read from the SSIVECT bits clears the corresponding SSI_FLAG[4-1] bit in the SSIF register, corresponding to the source vector of the system software interrupt.** **Note: The SSIR[4-1] interrupt has the following priority order:** SSIR1 has the highest priority. SSIR4 has the lowest priority.
		0	No software interrupt is pending.
		1h	A software interrupt has been generated by writing the correct key value to The SSIR1 register.
		2h	A software interrupt has been generated by writing the correct key value to The SSIR2 register.
		3h	A software interrupt has been generated by writing the correct key value to The SSIR3 register.
		4h	A software interrupt has been generated by writing the correct key value to The SSIR4 register.
		5h-FFh	Reserved

2.5.1.51 System Software Interrupt Flag Register (SSIF)

The SSIF register, shown in Figure 2-58 and described in Table 2-70, contains software interrupt flag status information.

Figure 2-58. System Software Interrupt Flag Register (SSIF) (offset = F8h)

LEGEND: R/W = Read/Write; R = Read only; C = Clear; -*n* = value after reset

Table 2-70. System Software Interrupt Flag Register (SSIF) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	SSI_FLAG[4-1]		System software interrupt flag[4-1]. This flag is set when the correct SSKEY is written to the SSIR register[4-1]. **Note: A read from the SSIVEC register clears the corresponding SSI_FLAG[4-1] bit in the SSIF, corresponding to the source vector of the system software interrupt.**
		0	*Read:* No IRQ/FIQ interrupt was generated since the bit was last cleared. *Write:* The bit is unchanged.
		1	*Read:* An IRQ/FIQ interrupt was generated. *Write:* The bit is cleared to 0.

2.5.2 Secondary System Control Registers (SYS2)

This section describes the secondary frame of system registers. The start address of the secondary system module frame is FFFF E100h. The registers support 8-, 16-, and 32-bit writes. The offset is relative to the system module frame start address.

Table 2-71 contains a list of the secondary system control registers.

NOTE: All additional registers in the secondary system frame are reserved.

Table 2-71. Secondary System Control Registers

Offset	Acronym	Register Description	Section
00h	PLLCTL3	PLL Control Register 3	Section 2.5.2.1
08h	STCLKDIV	CPU Logic BIST Clock Divider	Section 2.5.2.2

2.5.2.3 ECP Control Register 1 (ECPCNTL1)

The ECP register, shown in Figure 2-61 and described in Table 2-74, configures the ECLK2 pin in functional mode.

NOTE: ECLK2 Functional mode configuration.

The ECLK2 pin must be placed into Functional mode by setting the ECPCLKFUN bit to 1 in the SYSPC1 register before a clock source will be visible on the ECLK pin.

Figure 2-61. ECP Control Register 1 (ECPCNTL1) (offset = 28h)

ECPDIV	
R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 2-74. ECP Control Register 1 (ECPCNTL1) Field Descriptions

Bit	Field	Value	Description
31-28	ECP_KEY		Enable ECP clock logic for ECLK2.
		Ah	Clock functionality of ECP clock is enabled.
		Others	Clock functionality of ECP clock is disabled.
27-25	Reserved	0	Reads return 0. Writes have no effect.
24	ECPSSEL		This bit allows the selection between VCLK and OSCIN as the clock source for ECLK2.
		0	VCLK is selected as the ECP clock source.
		1	OSCIN is selected as the ECP clock source.
23	ECPCOS		ECP continue on suspend. **Note: Suspend mode is entered while performing certain JTAG debugging operations.**
		0	ECLK output is disabled in suspend mode. ECLK output will be shut off and will not be seen on the I/O pin of the device.
		1	ECLK output is not disabled in suspend mode. ECLK output will not be shut off and will be seen on the I/O pin of the device.
22-16	Reserved	0	Reads return 0. Writes have no effect.
15-0	ECPDIV	0-FFFFh	ECP divider value. The value of ECPDIV bits determine the external clock (ECP clock) frequency as a ratio of VBUS clock or OSCIN as shown in the formula: $ECLK = \frac{VCLK\,or\,OSCIN}{(ECPDIV + 1)}$

2.5.2.5 Peripheral Asynchronous Clock Configuration 1 Register (VCLKACON1)

This register is shown in Figure 2-63 and described in Table 2-76.

Figure 2-63. Peripheral Asynchronous Clock Configuration 1 Register (VCLKACON1) [offset = 40h]

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 2-76. Peripheral Asynchronous Clock Configuration 1 Register (VCLKACON1) Field Descriptions

Bit	Field	Value	Description
31-27	Reserved	0	Reads return 0. Writes have no effect.
26-24	VCLKA4R		Clock divider for the VCLKA4 source. Output will be present on VCLKA4_DIVR.
			VCLKA4 domain will be enabled by writing to the CDDIS register and VCLKA4_DIV_CDDIS bit. It can inferred that VCLKA4_DIV clock is disabled when VCLKA4 clock is disabled.
		0	The ratio is VCLKA4 divided by 1.
		:	:
		7h	The ratio is VCLKA4 divided by 8.
23-21	Reserved	0	Reads return 0. Writes have no effect.
20	VCLKA4_DIV_CDDIS		Disable the VCLKA4 divider output.
			VCLKA4 domain will be enabled by writing to the CDDIS register.
		0	Enable the prescaled VCLKA4 clock on VCLKA4_DIVR.
		1	Disable the prescaled VCLKA4 clock on VCLKA4_DIVR.
19-16	VCLKA4S		Peripheral asynchronous clock4 source.
		0	Clock source0 is the source for peripheral asynchronous clock4.
		1h	Clock source1 is the source for peripheral asynchronous clock4.
		2h	Clock source2 is the source for peripheral asynchronous clock4.
		3h	Clock source3 is the source for peripheral asynchronous clock4.
		4h	Clock source4 is the source for peripheral asynchronous clock4.
		5h	Clock source5 is the source for peripheral asynchronous clock4.
		6h	Clock source6 is the source for peripheral asynchronous clock4.
		7h	Clock source7 is the source for peripheral asynchronous clock4.
		8h-Fh	VCLK or a divided VCLK is the source for peripheral asynchronous clock4. See the device-specific data manual for details.
15-0	Reserved	109h	Reserved

NOTE: Non-implemented clock sources should not be enabled or used. A list of the available clock sources is shown in the Table 2-29.

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 2-78. Clock Slip Control Register (CLKSLIP) Field Descriptions

Bit	Field	Value	Description
31-14	Reserved	0	Reads return 0. Writes have no effect.
13-8	PLL1_RFSLIP_FILTER_COUNT		PLL RFSLIP down counter programmed value. Count is on 10M clock.
			On reset, counter value is 0. Counter must be programmed to a non-zero value and enabled for the filtering to be enabled.
		0	Filtering is disabled.
		1h	Filtering is enabled. Every slip is recognized.
		2h	Filtering is enabled. The slip must be at least 2 HF LPO cycles wide in order to be recognized as a slip.
		:	:
		3Fh	Filtering is enabled. The RFSLIP must be at least 63 HF LPO cycles wide in order to be recognized as a slip.
7-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	PLL1_RFSLIP_FILTER_KEY		Enable the PLL RFSLIP filtering.
		5h	On reset, the PLL RFSLIP filter is disabled and the PLL RFSLIP passes through.
		Fh	This is an unsupported value. You should avoid writing this value to this bit field.
		Others	PLL RFSLIP filtering is enabled. Recommended to program Ah in this bit field. Enabling of the PLL RFSLIP occurs when the KEY is programmed and a non-zero value is present in the COUNT field.

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 2-79. Clock Slip Register (CLKSLIP) Field Descriptions

Bit	Field	Value	Description
31-28	Reserved	0	Reads return 0. Writes have no effect.
27-24	Reserved	0-Fh	Reads return 0 or 1 and depends on what is written in privileged mode. The functionality of this bit is unavailable in this device.
23-20	Reserved	0	Reads return 0. Writes have no effect.
19-16	Reserved	0-Fh	Reads return 0 or 1 and depends on what is written in privileged mode. The functionality of this bit is unavailable in this device.
15-12	Reserved	0	Reads return 0. Writes have no effect.
11-8	IP2_ECC_KEY		ECC Error Enable Key for PS_SCR_M master. There is an ECC Evaluation block inside the CPU Interconnect Subsystem responsible for ECC correction and detection on the data path for transactions initiated by the PS_SCR_M master. If an ECC error (either single-bit or double-bit error) is detected, then the corresponding error signal is asserted if ECC enable key written to IP2_ECC_KEY is Ah.
		Others	Disable ECC error generation for ECC errors detected on PS_SCR_M master by the CPU Interconnect Subsystem.
		Ah	Enable ECC error generation for ECC errors detected on PS_SCR_M master by the CPU Interconnect Subsystem.
7-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	IP1_ECC_KEY		ECC Error Enable Key for DMA Port A master. There is an ECC Evaluation block inside the CPU Interconnect Subsystem responsible for ECC correction and detection on the data path for transactions initiated by the DMA Port A master. If an ECC error (either single-bit or double-bit error) is detected, then the corresponding error signal is asserted if ECC enable key written to IP1_ECC_KEY is Ah.
		Others	Disable ECC error generation for ECC errors detected on DMA Port A master by the CPU Interconnect Subsystem.
		Ah	Enable ECC error generation for ECC errors detected on DMA Port A master by the CPU Interconnect Subsystem.

Bit	Field	Value	Description
31-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	EFC_INSTR_WEN		Enable user write of 4 EFUSE controller instructions.
			SYS module generates the enable signal that will be tied to OCP_FROM_WRITE_DISABLE on efuse controller port.
		Ah	Writing of instructions (Program, ProgramCRA, RunAutoload, and LoadFuseScanchain) to EFC is allowed.
		Others	Writing of instructions (Program, ProgramCRA, RunAutoload, and LoadFuseScanchain) in EFC registers is blocked.

2.5.2.10 Die Identification Register Lower Word (DIEIDL_REG0)

The DIEIDL_REG0 register is a duplicate of the DIEIDL register, see Section 2.5.1.28. The DIEIDL_REG0 register, shown in Figure 2-68 and described in Table 2-81, contains information about the die wafer number, and X, Y wafer coordinates.

2.5.3 Peripheral Central Resource (PCR) Control Registers

This section describes the Peripheral Central Resource (PCR) control registers. The are three PCRx in this microcontroller. The start address of the PCR1 register frame is FFFF 1000h. The start address of the PCR2 register frame is FCFF 1000h. The start address of the PCR3 register frame is FFF7 8000h. Table 2-85 lists the registers in the PCR, which are used to configure the following main functionalities:

- Protection control to the peripherals in PCS (Peripheral Memory) and PS (Peripheral) regions.
- Powerdown control to the peripherals in PCS (Peripheral Memory) and PS (Peripheral) regions.
- Powerdown control to the CoreSight debug peripherals in debug frame region from FFA0 0000h to FFAF FFFFh.
- Master-ID Filtering control to the peripherals in PS (Peripheral), PPS (Privileged Peripheral) , PPSE (Privileged Peripheral Extended) regions.
- Master-ID Filtering control to the peripheral memories in PCS (Peripheral Memory), and PPCS (Privileged Peripheral Memory) regions.

The following sections provide detailed information about these registers. Not all chip selects exist on this device.

Table 2-85. Peripheral Central Resource Control Registers

Offset	Acronym	Register Description	Section

2.5.3.5 Peripheral Protection Set Register 0 (PPROTSET0)

There is one bit for each quadrant for PS0 to PS7.

The following are the ways that quadrants are used within a PS frame:

a. The slave uses all the four quadrants.

   Only the bit corresponding to the quadrant 0 of PSn is implemented. It protects the whole 1K-byte frame. The remaining three bits are not implemented.

b. The slave uses two quadrants.

   Each quadrant has to be in one of these groups: (Quad 0 and Quad 1) or (Quad 2 and Quad 3).

   For the group Quad0/Quad1, the bit quadrant 0 protects both quadrants 0 and 1. The bit quadrant 1 is not implemented.

   For the group Quad2/Quad3, the bit quadrant 2 protects both quadrants 2 and 3. The bit quadrant 3 is not implemented

c. The slave uses only one quadrant.

   In this case, the bit, as specified in Table 2-90, protects the slave.

The above arrangement is true for all the peripheral selects (PS0 to PS31), presented in Section 2.5.3.6 - Section 2.5.3.12. This register holds bits for PS0 to PS7 and is shown in Figure 2-76 and described in Table 2-90.

NOTE: Writes to unimplemented bits have no effect and reads are 0.

2.5.3.17 Peripheral Power-Down Set Register 0 (PSPWRDWNSET0)

There is one bit for each quadrant for PS0 to PS7. Each bit of this register corresponds to the bit at the same index in the corresponding PPROT register in that they relate to the same peripheral. These bits are used to power down/power up the clock to the corresponding peripheral.

For every bit implemented in the PPROT register, there is one bit in the PSnPWRDWN register, except when two peripherals (both in PS area) share buses. In that case, only one Power-Down bit is implemented, at the position corresponding to that peripheral whose quadrant comes first (the lower numbered).

The ways in which quadrants can be used within a frame are identical to what is described under PPROTSET0, Section 2.5.3.5.

This arrangement is the same for bits of PS8 to PS31, presented in Section 2.5.3.18 - Section 2.5.3.24. This register holds bits for PS0 to PS7. This register is shown in Figure 2-88 and described in Table 2-102.

NOTE: Only those bits that have a slave at the corresponding bit position are implemented. Writes to unimplemented bits have no effect and reads are 0.

		1	*Read:* The clock to the peripheral select quadrant is inactive. *Write:* The corresponding bit in PSPWRDWNSET1 and PSPWRDWNCLR1 registers is cleared to 0.

2.5.3.23 Peripheral Power-Down Clear Register 2 (PSPWRDWNCLR2)

There is one bit for each quadrant for PS16 to PS23. The protection scheme is described in Section 2.5.3.17. This register is shown in Figure 2-94 and described in Table 2-108.

NOTE: Only those bits that have a slave at the corresponding bit position are implemented. Writes to unimplemented bits have no effect and reads are 0.

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 2-114. MasterID Diagnostic Control Register (MSTIDDIAGCTRL) Field Descriptions

Bit	Field	Value	Description
31-12	Reserved	0	Reads return 0. Writes have no effect.
11-8	DIAG_CMP_VALUE		Diagnostic Compare Value. The value stored in this register is compared against the programmed master-ID register bits for all accesses. In diagnostic mode, the master-ID register selection depends on the DIAG_CMP_VALUE instead of the input 4-bit master-ID generated by the interconnect. Any mismatch will be signaled to the bus master as a bus error. After the diagnostic mode is enabled in DIAG_MODE_ENA register and a diagnostic compare value is programmed into the DIAG_CMP_VALUE register, the application must issue a dummy diagnostic write access to any one of the peripherals to cause a diagnostic check. For example, if all master-ID protection registers listed from address 0x300-0x5DC are programmed to block master-ID 5 from write access to the peripherals, then the application can program the DIAG_CMP_VALUE to 5. The application can use the CPU (whose master-ID is 0) to issue a dummy write access to any peripheral to cause master-ID violation during diagnostic mode instead of using the bus master whose master-ID is 5 to perform this write access.
		Ah	*Read:* The master-ID check is enabled. *Write:* Enable master-ID check.
		Others	*Read:* The master-ID check is disabled. *Write:* Disable master-ID check.
7-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	DIAG_MODE_ENA		Diagnostic Mode Enable. This is a 4-bit key for enabling Diagnostic Mode. This key must be programmed with 1010 to enable Diagnostic Mode.
		Ah	*Read:* The diagnostic mode is enabled. *Write:* Enable diagnostic mode.
		Others	*Read:* The diagnostic mode is disabled. *Write:* Disable diagnostic mode.

2.5.3.30 Peripheral Frame 0 MasterID Protection Register_L (PS0MSTID_L)

There is one bit for each quadrant for PS0 to PS31.

NOTE: If a module occupies two quadrants, then only the lower quadrant register is used to enable or disable the masterID. The upper quadrant register remains zeros.

The following are the ways that quadrants are used within a PS frame:

a. The slave uses all the four quadrants.

   Only the bit corresponding to the quadrant 0 of PSn is implemented. It protects the whole 1K-byte frame. The remaining three bits are not implemented.

b. The slave uses two quadrants.

   Each quadrant has to be in one of these groups: (Quad 0 and Quad 1) or (Quad 2 and Quad 3).

   For the group Quad0/Quad1, the bit quadrant 0 protects both quadrants 0 and 1. The bit quadrant 1 is not implemented.

   For the group Quad2/Quad3, the bit quadrant 2 protects both quadrants 2 and 3. The bit quadrant 3 is not implemented

c. The slave uses only one quadrant.

   In this case, the bit, as specified in Table 2-115, protects the slave.

The above arrangement is true for all the peripheral selects (PS0 to PS31), presented in Section 2.5.3.31 - Section 2.5.3.32. This register holds bits for PS0 and is shown in Figure 2-101 and described in Table 2-115.

Table 2-115. Peripheral Frame 0 MasterID Protection Register_L (PS0MSTID_L) Field Descriptions

Bit	Field	Value	Description
31-16	PS0_QUAD1_MSTID		MasterID filtering for Quadrant 1 of PS[0]. There are 16 bits for each quadrant in PS frame. Each bit corresponds to a master-ID value. For example, bit 0 corresponds to master-ID 0 and bit 15 corresponds to master-ID 15. These bits set the permission for maximum of 16 masters to address the peripheral mapped in each of the quadrant. The following examples shows the usage of these register bits. (a) If bits 15:0 are 1010_1010_1010_1010, then the peripheral that is mapped to Quadrant 0 of PS[0] can be addressed by Masters with Master-ID equals to 1,3,5,7,9,11,13,15. (b) if bits 15:0 are 0000_0000_0000_0001, then the peripheral that is mapped to Quadrant 0 of PS[0] can only addressed by the master with the Master-ID equal to 0.
		0	*Read:* The corresponding master-ID is not permitted to access the peripheral mapped to this quadrant. *Write:* Disable the permission of the corresponding master to access the peripheral mapped to this quadrant.
		1	*Read:* The corresponding master-ID is permitted to access the peripheral mapped to this quadrant. *Write:* Enable the permission of the corresponding master to access the peripheral mapped to this quadrant.

SCR Control Module (SCM)

This chapter describes the SCR control module (SCM). SCR is the CPU Interconnect Subsystem.

Topic **Page**

3.1 Overview 253
3.2 Module Operation 255
3.3 How to Use SCM 257
3.4 SCM Registers 260

Copyright © 2018, Texas Instruments Incorporated

3.1 Overview

The SCR (Switch Central Resource) Control Module (SCM) provides a means to control and monitor the main interconnect.

Interconnect hardware checker performs four major functional checks on interconnect:

- Arbitration
- Timeout
- Protocol conversion
- Parity on control / address signals

Any of these errors will force the interconnect to trigger an error event to ESM group 1 (see ESM group1 mapping). It is recommended that you should set the interconnect error to toggle ESM pin action. The reason is that if an error occurs and CPU can not access to Flash or RAM to run diagnostic or retry, external monitoring ASIC can be notified by ESM error pin.

3.1.1 Features

The following main features are supported:

- Compares the real time running counter of transaction command request to transaction command accept from each initiator agent (IA - is the bus master that initiates transactions to the interconnect. Refer to the Interconnect chapter for more definition and connection) with the REQ2ACCEPT threshold value. if the real time counter is equal or larger than the threshold, the SCM will trigger an error event to ESM. A corresponding status bit of the corresponding IA will also be set.
- Compares the real time running counter of transaction command request accepted to transaction command response accepted from each IA with the REQ2RESP threshold value. If the real time counter is equal or larger than the threshold, the SCM will trigger an error event to ESM. A corresponding status bit of the corresponding IA will also be set.
- Provides a control key to clear the time out counters overrun inside hardware checker of the interconnect. This control bit will clear all registers and make the timeout module available to restart properly.
- Provides a control key to start a self-test sequence of the interconnect hardware checker.
- Provides a control key to clear global error flag inside interconnect hardware checker.
- Captures the active status of each IA and target agent (TA - is the bus slave receives transaction request from interconnect and responses to it. Refer to the Interconnect chapter of the TRM for more definition and connection) of the interconnect. The active status bit indicates that there is still pending transactions inside interconnect.
- Provides the ability to override parity polarity of the interconnect hardware checker so that the parity detection logic can be self-tested.

3.1.2 System Block Diagram

Figure 3-1 shows the system level block diagram of SCM and interconnect (SCR).

SCM compares the transaction command request to transaction command accept (req2accept) counters and transaction command request to transaction command response (req2resp) counters of each initiator agent (IA) to the corresponding threshold values (programmable). If the req2accept or req2resp counters are larger than or equal to the threshold, SCM will generate error event to ESM module.

SCM can clear the req2accept and req2resp counters inside interconnect SCR. It can also initiate self-test sequence to make sure the hardware checker diagnostic logic is functioning properly.

Figure 3-1. System Level Block Diagram

n is the maximum number of IA. m is the maximum number of TA.

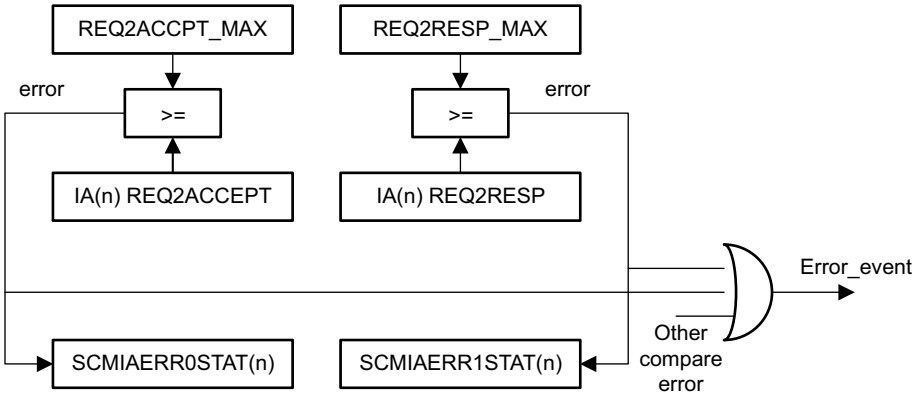
3.2 Module Operation

3.2.1 Block Diagram

Figure 3-2 shows the block diagram of SCM.

Figure 3-2. SCM Block Diagram

n is the maximum number of IA. m is the maximum number of TA.



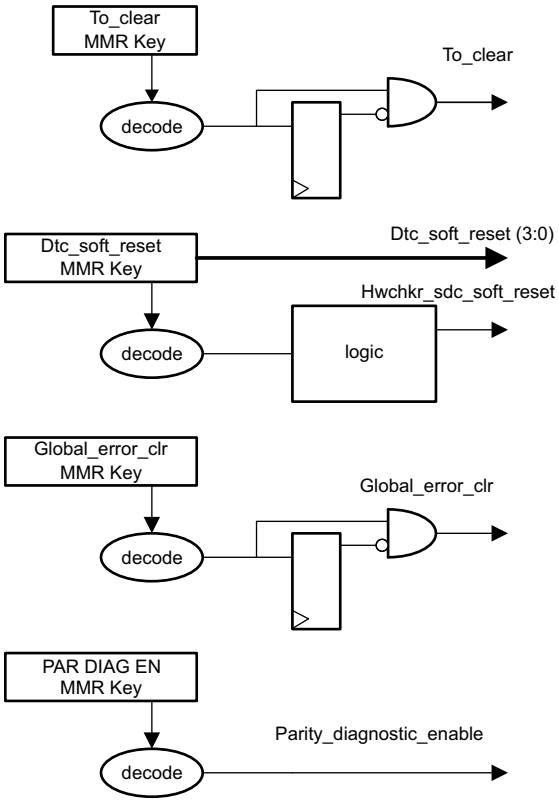
3.2.2 Timeout Threshold Compare Block

The threshold compare block (Figure 3-3) takes the real-time counters (command request to command accepted and command request to command response) from each IA of the interconnect hardware checker module and compare against the corresponding threshold value in SCM every cycle. If any IA comparison fails, the SCM module will update the corresponding status bit in SCMIAERR0STAT and SCMIAERR1STAT registers. SCMIAERR0STAT logs the time out error for command request to command accepted. SCMIAERR1STAT logs the time out error for command request to command response. Any status bit set in these two status registers will trigger an error event to ESM (Error Signaling Module) and will not trigger again until cleared by CPU.

Any of these status bits can be cleared by a privilege write to the individual bit. The write clear from CPU to these status bits will always take higher priority than setting of the status bits from the interconnect.

Copyright © 2018, Texas Instruments Incorporated

Figure 3-3. Timeout Threshold Compare



3.2.2.1 Interconnect Timeout Clearing Control Key

When the threshold compare block triggers a time out error, the ESM will be notified and can interrupt the main CPU. The interconnect hardware checker real-time counter needs to be reset to 0 in order to restart properly. Section 3.3 has recommendations on how you should react in this case. You can clear all the real time counter values inside interconnect hardware checker. This is necessary to restart the real time counter.

3.2.3 SCM Control Block

Figure 3-4 shows a block diagram of the SCM.

Figure 3-4. SCM Control Block

Copyright © 2018, Texas Instruments Incorporated

3.2.3.1 Control Key to invert Parity Polarity for Interconnect Hardware Checker Parity Detection Diagnostic

The interconnect receives parity bits associated with input control and address signals and does the parity checking. The interconnect also generates parity bits for corresponding control and address signals. To test the parity checking logic, the SCM can invert the parity polarity bit to the interconnect to purposely creates a fail or pass parity checking condition.

Section 3.3 has recommendations on how you should test the parity detection logic inside interconnect hardware checker.

3.2.3.2 Global Error Clearing Control Key

Interconnect subsystem triggers global error in case of any of the following errors happen:

- Parity checking error on any bus master.
- Arbitration error.
- Protocol conversion error.
- Self-test fail in self-test diagnostic mode.

A global error from interconnect subsystem can result in non-recoverable condition for the device. It is recommended that user issues a global error clear by writing 0xA to the GLOBAL_ERR_CLR of the SCMCNTRL register in conjunction to system reset.

3.2.3.3 Interconnect Hardware Checker Self-test

Interconnect hardware checker performs four major diagnostic checks on interconnect:

- Arbitration
- Timeout
- Protocol conversion
- Parity on control / address signals

Thus, it is necessary to be able to do self-test of interconnect hardware checker logic whenever you decide at appropriate time in the application control loop. The self-test logic will create normal and erroneous transaction from each master to each slave according to the bus connection matrix to verify that the hardware checker properly functioning. See Section 3.3.2 for detail on how to start self-test.

3.3 How to Use SCM

3.3.1 How to Check the Parity Compare Logic

Interconnect has associated parity bits for control and address bit of the communication bus. Parity check is done for all control and address input. Parity generation is done for all control and address output.

For fail safety reason, parity checking logic needs to be tested at your choice of time in their control loop.

To enable the parity detection test, you should switch to privilege mode and write 0xA to SCMCNTRL[27:24] control register. This will invert the parity polarity and testing for only one cycle. The SCM module will reset the control key back to 0x5 once it triggers an inversion parity polarity to interconnect hardware checker. Since parity polarity is inverted only inside interconnect, the interconnect will flag parity error for input control and address signals. The interconnect also output an inverted polarity for output control and address signals. Thus, master and slave IP connected to interconnect could potentially generate parity error as well. This way, the corresponding parity detection logic in master and slave IP can be tested at the same time. You should clear all parity error status bits residing in master IP, slave IP, or interconnect status registers.

Note that the hardware only does parity inversion check in one cycle so that it does not block out CPU access to Flash and RAM on subsequence cycle.

Copyright © 2018, Texas Instruments Incorporated

3.3.2 How to Initiate Self-test Sequence

It is necessary to be able to do self-test of the interconnect hardware checker logic to detect residual faults when you decide at appropriate time in the application control loop. The self-test logic will create normal and erroneous transaction from each master to each slave according to the bus connection matrix to verify that the hardware checker and the interconnect functioning properly.

To initiate the self-test sequence, you should switch to privilege mode.

1. Software needs to ensure that MASK_SOFT_RESET control bit of the interconnect self-test control register (Interconnect SDC MMR offset at 0xFA00_0000[0]) is 0.
2. Software needs to ensure that GCLK1 is still running.
3. Software needs to ensure that all bus master connecting to interconnect should stop sending new transaction to interconnect. The hardware will make sure that all outstanding transaction will complete.
4. Software writes to SCM control register bit field DTC_SOFT_RESET a key value: 0xA to initiate self-test.
5. CPU0 and CPU1 must execute WFI instruction.
   a. At this point, the hardware will ensure that there is no outstanding transaction inside interconnect and will trigger self-test.
   b. While hardware checker self-test is ongoing, the CPU will be held in reset and released until self-test completes
6. Once self-test completes, CPU will boot up from 0x0 again and you need to read interconnect diagnostic register to inspect for any error detected during self-test. Refer to device technical reference manual for base address.

Copyright © 2018, Texas Instruments Incorporated

3.3.3 How to Configure Timeout Check

The threshold compare block takes the real time counters (command request to command accepted and command request to command response) from each IA of the interconnect hardware checker module and compare against the corresponding threshold value in SCM every cycle. If any IA comparison fails, the SCM module will update the corresponding status bit in SCMIAERR0STAT and SCMIAERR1STAT registers. SCMIAERR0STAT logs the time out error for command request to command accepted. SCMIAERR1STAT logs the time out error for command request to command response. Any status bit set in these two status registers will trigger an error event to ESM (Error Signaling Module) and will not trigger again until cleared by CPU.

You should configure the SCMTHRESHOLD control register to setup the command transaction request to command transaction acceptance threshold as well as command transaction request to command transaction response threshold. It is recommended that you use the default reset value of decimal 1024 (400h) for the SCMTHRESHOLD control registers. However, you can change this values depending on application depending on the number of IA and TA required by the interconnect.

When threshold compare block triggers a time out error, the error will be sent to the ESM module resulting in an interrupt exception to the CPU.

When interrupted, it is recommended that you read the SCMIAERR0STAT and SCMIAERR1STAT to find out which master or slave having the time out issue and clear the real time counter inside interconnect. Then, issue a retry on the transaction

1. If the retry is successful, you can resume operation.
2. If the retry fails because time out still occurs, you should trigger a self-test to check for any issue of interconnect. If self-test fails or time out error still occurs after passing self-test, you should try to shut down the system in a safe way. In the case that interconnect has issue and blocking access to Flash or RAM, ESM pin action can not be reset thus external monitoring ASIC will be notified.

To clear real time counters inside SCR, you should switch to privilege mode and write Ah to the SCMCNTRL[3:0] control register. The SCM module will reset the control key back to 5h once it triggers a clear command to interconnect hardware checker. The interconnect hardware checker real time counter needs to be reset to 0 in order to restart properly.

3.4 SCM Registers

The SCM registers are listed in Table 3-1 . Each register begins on a word boundary. The registers support 8-, 16-, and 32-bit accesses. The address offset is specified from the base address of FFFF 0A00h.

Registers are accessed through a dedicated MMR interface. Support only read, write, and write non-posted. Read and write are always returning response status. A write to reserved bits has no effect.

If there is soft error or any other event that results in an unsupported command such as readlink-write conditional or broadcast bus transactions, the MMR interface will return with response bus error for unsupported command. Software should check for valid address and whether the target is in low power mode or not prior to issue a retry access.

Table 3-1. SCM Registers

Offset	Acronym	Register Description	Section

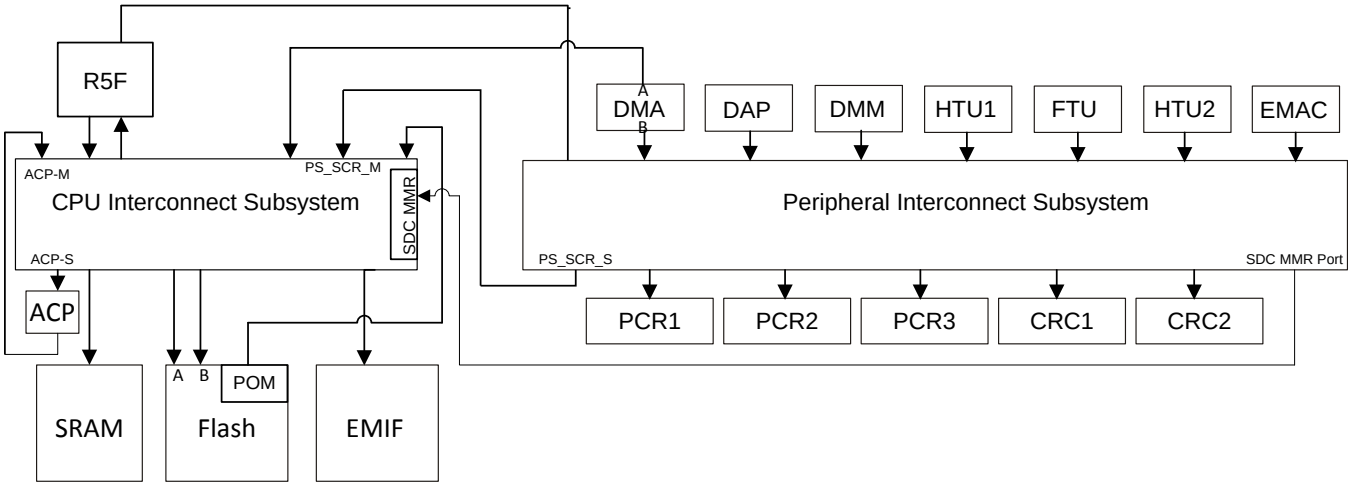
Interconnect

This chapter describes the two interconnects in the microcontroller.

Topic **Page**

4.1 Overview 266
4.2 Peripheral Interconnect Subsystem 266
4.3 CPU Interconnect Subsystem 268
4.4 SDC MMR Registers 272

Copyright © 2018, Texas Instruments Incorporated



4.1 Overview

The interconnect is a bus matrix which interconnects the CPU cores, System DMA, other bus masters and device specific slaves within the microcontroller. There are two interconnects in the microcontroller: the CPU Interconnect Subsystem and the Peripheral Interconnect Subsystem. The interconnects direct the access requests by the masters by providing decoding, arbitration, and routing of the requests to the various slaves.

4.1.1 Block Diagram

Figure 4-1 is a block diagram of the Interconnects implemented in this family of microcontrollers.

Figure 4-1. Interconnect Block Diagram

4.2 Peripheral Interconnect Subsystem

There are masters and slaves connected to the Peripheral Interconnect Subsystem. The Peripheral Interconnect Subsystem is not a full cross-bar. Not all masters can access to all slaves. Table 4-1 lists the implemented point-to-point connections between the masters and slaves.

Table 4-1. Bus Master / Slave Connectivity for Peripheral Interconnect Subsystem

Masters	Master ID to PCRx	Access Mode	Slaves on Peripheral Interconnect Subsystem

4.2.1 Accessing PCRx and CRCx Slave

System peripherals can be accessed via the PCR1 slave port. User peripherals can be accessed via either the PCR2 or PCR3 slave ports. Refer to the datasheet for information on what peripherals are available through each PCR. Peripheral Central Resource (PCR) is responsible to further decode the slave address to select the desired peripheral.

There are two CRC modules implemented in the device. Both are direct slaves to the Peripheral Interconnect Subsystem.

4.2.2 Accessing SDC MMR Port Slave

Safety Diagnostic Controller (SDC) MMR Port is a slave to the Peripheral Interconnect Subsystem to access the safety diagnostic related control and status registers of the CPU Interconnect Subsystem. Table 4-2 lists the CPU Interconnect Subsystem SDC register bit field mapping.

Table 4-2. CPU Interconnect Subsystem SDC Register Bit Field Mapping

Register Name	Bit 0	Bit 1	Bit 2	Bit 3	Bit 4	Bit 5	Bit 6	Remark
ERR_GENERIC_ PARITY	PS_SCR_ M	POM	DMA_ PORTA	CPU AXI-M	Reserved	ACP-M	Reserved	Each bit indicates the transaction processing block inside the interconnect corresponding to the master that is detected by the interconnect checker to have a fault. Error related to parity mismatch in the incoming address.
ERR_UNEXPECTED_ TRANS	PS_SCR_ M	POM	DMA_ PORTA	CPU AXI-M	Reserved	ACP-M	Reserved	Error related to unexpected transaction sent by the master.

ERR_TRANS_ SIGNATURE	PS_SCR_ M	POM	DMA_ PORTA	CPU AXI-M	Reserved	ACP-M	Reserved	Error related to mismatch on the transaction signature.
ERR_TRANS_TYPE	PS_SCR_ M	POM	DMA_ PORTA	CPU AXI-M	Reserved	ACP-M	Reserved	Error related to mismatch on the transaction type.
ERR_USER_PARITY	PS_SCR_ M	POM	DMA_ PORTA	CPU AXI-M	Reserved	ACP-M	Reserved	Error related to mismatch on the parity.
SERR_UNEXPECTED_ MID	L2 SRAM Wrapper	L2 Flash Wrapper Port A	L2 Flash Wrapper Port B	EMIF	Reserved	CPU AXi-S	ACP-S	Each bit indicates the transaction processing block inside the interconnect corresponding to the slave that is detected by the interconnect checker to have a fault. Error related to mismatch on the master ID.
SERR_ADDR_ DECODE	L2 SRAM Wrapper	L2 Flash Wrapper Port A	L2 Flash Wrapper Port B	EMIF	Reserved	CPU AXi-S	ACP-S	Error related to mismatch on the most significant address bits.
SERR_USER_PARITY	L2 SRAM Wrapper	L2 Flash Wrapper Port A	L2 Flash Wrapper Port B	EMIF	Reserved	CPU AXi-S	ACP-S	Error related to mismatch on the parity of the most significant address bits.

4.2.3 Accessing Other Slaves via PS_SCR_S

In order for some of the masters connected to the Peripheral Interconnect Subsystem to access the slaves such as L2 Flash and L2 SRAM in the CPU Interconnect Subsystem, their requests are first funneled into the PS_SCR_S slave where it then becomes a master on the CPU Interconnect Subsystem as PS_SCR_M. The request appearing on the PS_SCR_M is then decoded and routed to the intended slave by the CPU Interconnect Subsystem.

Copyright © 2018, Texas Instruments Incorporated

4.3 CPU Interconnect Subsystem

The masters and slaves are connected to the CPU Interconnect Subsystem. The CPU Interconnect Subsystem is not a full cross-bar. Not all masters can access to all slaves. Table 4-3 lists the implemented point to point connections between the masters and slaves. What is also unique to the CPU Interconnect Subsystem is that the interconnect and all the masters and slaves that connect to it constitute one safety island where all transactions to and from the masters and slaves are protected on the data path by ECC. Address and control signals on all transactions are protected by parity. In addition, the CPU Interconnect Subsystem contains a built-in hardware Safety Diagnostic Checker on each master and slave interface where it constantly monitors the integrity of traffics between the masters and slaves. The CPU Interconnect Subsystem also has a self-test capability that when enabled will inject test stimulus onto each master and slave interface and diagnose the interconnect itself.

Table 4-3. Bus Master / Slave Connectivity for CPU Interconnect Subsystem

Masters	Access Mode	Slaves on CPU Interconnect Subsystem					
		L2 Flash Port A	L2 Flash Port B	L2 SRAM	CPU AXI-S	EMIF	ACP-S
CPU Read	User/Privilege	Yes	Yes	Yes	Yes	Yes	No
CPU Write	User/Privilege	No	No	Yes	Yes	Yes	No
DMA Port A	User	No	Yes	Yes	No	Yes	Yes
POM	User	No	No	Yes	No	Yes	Yes
PS_SCR_M	See (1)	No	Yes	Yes	No	Yes	Yes
ACP_M	See (1)	No	No	Yes	No	No	No

(1) The access mode for PS_SCR_M depends on which master on the peripheral side (HTU1, HTU2, FTU, DMM, DAP, and EMAC), see Table 4-1, is accessing the memories on the CPU side. The ACP_M access mode reflects the PS_SCR_M access mode.

4.3.1 Slave Accessing

4.3.1.1 Accessing L2 Flash Slave

There are two flash slave ports which allow possible parallel requests by the masters to different flash banks at the same time. There are two flash banks of 2Mbytes each implemented in the device. It is possible for CPU0 to access one flash bank via Flash PortA while DMA accesses to the other flash bank via Flash PortB.

4.3.1.2 Accessing L2 SRAM Slave

In order for the DMA PortA, POM and PS_SCR_M to access the L2 SRAM, their requests are first funneled into ACP-S slave port. Accelerated Coherency Port (ACP) is a hardware which provides memory coherency checking between each CPU in the Cortex-R5 group and an external master. Accesses made by the DMA PortA, POM and PS_SCR_M are first checked by the ACP coherency hardware to see if the write data is already in the CPU's data cache. When a write from the DMA PortA, POM and PS_SCR_M appears on the ACP slave, the ACP records some information about it and forward the write transactions to the L2 SRAM on the ACP-M master port. When the memory system sends the write response on the ACP-M master port, the ACP records the response and recalls if the transaction was coherent. If the transaction is not coherent, the ACP forwards the response to the bus master on the ACP-S slave port. If the transaction is coherent, the ACP first sends coherency maintenance operations to the CPU's data cache controller for the addresses spanned by the write transaction, and wait until the cache controller has acknowledged that all necessary coherency maintenance operations have been carried out to forward the write response to the ACP-S slave port. CPUs have direct access to the L2 SRAM.

4.3.1.3 Accessing EMIF Slave

All bus masters on the CPU Interconnect Subsystem have a point to point connection to the EMIF slave without going through ACP for coherency check. Coherency maintenance on the EMIF between the CPU and other masters will need to be handled by software.

Copyright © 2018, Texas Instruments Incorporated

4.3.1.4 Accessing Cache Memories

Both the instruction and data caches of theCPU are memory mapped in the device and can be accessed via the AXI-S slave port. Only the CPU core has point to point connection to the AXI-S slave port.

4.3.2 ECC Generation and Evaluation

CPU core contains the built-in ECC generation and evaluation logic for its AXI interface. Therefore, CPU will generate the ECC checksum along with its write data. The write data and the corresponding ECC checksum are transported by the interconnect to the selected slave such as L2 SRAM. When CPU core performs a read from a slave, the slave returns the data and the corresponding ECC checksum. Upon receiving the data and the ECC checksum, the CPU will evaluate the integrity of the data by performing the ECC check. ECC errors detected on the CPU's AXI interface are exported by the CPU to its event bus output. The error signals if enabled and the corresponding error addresses are first routed to the Error Profiling Controller (EPC) module. EPC is used to record different single bit error addresses in a Content Addressable Memory (CAM). The main purpose of the EPC module is to enable the system to tolerate a certain amount of ECC correctable errors on the same address repeated in the memory system with minimal runtime overhead. If an ECC error is generated on a repeating address, the EPC will not raise an error to ESM module. This tolerance avoids the application to handle the same error when the code is in a repeating loop. See EPC chapter for more information.

DMA PortA and PS_SCR_M masters do not have built-in ECC generation and evaluation logic. Therefore, the CPU Interconnect Subsystem contain a standalone ECC generation and evaluation logic for each DMA PortA and PS_SCR_M master. Write transactions initiated by the DMA PortA and PS_SCR_M masters are first treated by the ECC block to generate the ECC checksum before transporting to the final destination. For read transactions, the data and ECC checksum returned by the slaves will pass through the ECC block for data integrity evaluation.

ECC errors detected are also routed to the Error Profiling Controller (EPC) module. In order for the standalone ECC block to assert the error signals to the EPC, the error enable key must be first set in the IP1ECCERREN register of the SYS2 module.

NOTE: To enable error signal assertion to the ESM for ECC errors detected for DMA, the application must write 0xA to the IP1_ECC_KEY bits. To enable error signal assertion to the ESM for ECC errors detected for PS_SCR_M, the application must write 0xA to the IP2_ECC_KEY bits.

4.3.3 Safety Diagnostic Checker

For each master and slave interface in the CPU Interconnect Subsystem, there is a runtime Safety Diagnostic Checker. The hardware checker continuously watches transactions flowing through the interconnect and ensuring they are non corrupted at all time. If a mismatch is detected between an ongoing transaction and the expected transaction flow then an error is asserted to the ESM Group 1. Types of errors are recorded in the SDC MMR registers. See Section 4.4 for all the registers. Once an error is detected and the error type is logged, the application will clear the runtime diagnostic errors by writing an 0xA key to the GLOBAL_ERROR_CLR bits of the SCMCNTRL register in the SCR Control Module (SCM). See the SCM Chapter for more information.

Copyright © 2018, Texas Instruments Incorporated

4.3.4 Interconnect Self-test

CPU Interconnect Subsystem can be put into self-test. When in self-test, the self-test logic will apply test stimulus to each master and slave interface. If an error is detected, the type of error for the corresponding interface is logged. An error is asserted to ESM Group 3 if the self-test does not complete successfully.

NOTE: Application must only launch CPU Interconnect Subsystem self-test when there are no bus transactions from any masters including the CPU cores. While in self-test, the interconnect can not service any requests. Bus master requests can be lost or corrupted. It is recommend that the self-test is only exercised as part of the device initialization before any master is setup by the CPU.

To launch the self-test, the applicable must follow the below sequence:

1. Write 0xA key to the DTC_ERROR_RESET bits of the SCMCNTRL register in the SCM module.
2. CPU executes WFI instruction to put itself in idle state. The start of self-test is gated by the idle state of the CPU.
3. When both step 1 and 2 are met, the self-test will start. While self-test is on-going, the CPU cores is forced into reset. Note that reset is only held to the CPU cores while the rest of the system is not.
4. When self-test is complete, the DTC_ERROR_RESET bits is automatically reverted back to 0x5 as the reset value.
5. After the self-test is complete, a reset is applied to the CPU Interconnect Subsystem for 16 HCLK cycles. During this time, the CPU is also held in reset.
6. After the interconnect and the CPU comes out of the reset, normal code execution can then start. CPU can check the self-test status by reading the NT_OK bit and the PT_OK bit of the SDC_STATUS register. These two bits indicate if the negative test and positive self-test sequence have passed. In addition, if the self-test has failed, the error is asserted to the ESM module.

4.3.5 Interconnect Timeout

The CPU Interconnect Subsystem contains timeout counters to count the amount of time it is taking for a master request to be accepted by the slave and also to count the amount of time it takes from an accepted request to the slave response. There are two separate counters per master interface. When either the request-to-accept counter or the accept-to-response counter expires by the slave, a timeout error is asserted to the ESM. The counter threshold value beyond which the timeout error will be generated is programmable in the SCM module. When a timeout happens to an interface, the request-to-accept timeout error is captured in the SCM's SCMIAERR0STAT register and the accept-to-response timeout error is captured in the SCMIAERR1STAT. See Table 4-4 for the mapping between each interface to each bit field. Application needs to write 0xA key to the TO_CLEAR bits of the SCMCNTRL register to reset the timeout logic inside the CPU Interconnect Subsystem as part of the error handling in the ISR.

Copyright © 2018, Texas Instruments Incorporated

4.3.6 Interconnect Runtime Status

Both the CPU Interconnect Subsystem and the Peripheral Interconnect Subsystem will output its status on each master and slave interface to the SCM indicating if the interface is currently active. The status are captured in the SCMIASTAT register for the master interfaces and SCMTASTAT for the slave interfaces. See Table 4-4 for the mapping between each interface to each bit field.

Table 4-4. SCM Register Bit Mapping

Register	Bit 0	Bit 1	Bit 2	Bit 3	Bit 4	Bit 5	Bit 6	Bit 7	Remark
SCMIAERR0 STAT	PS_SCR _M	POM	DMA Port A	Reserved	Reserved	CPU AXI-M Read	CPU AXI-M Write	ACP-M	Each bit indicates the transaction processing block inside the interconnect corresponding to the master that is detected by the interconnect checker to have a fault. A timeout error when the time the request is issued by the master until the time the request is accepted by the slave has expired
SCMIAERR1 STAT	PS_SCR _M	POM	DMA Port A	Reserved	Reserved	CPU AXI-M Read	CPU AXI-M Write	ACP-M	A timeout error when the time the request is accepted by the slave until the time the request is responded by the slave has expired

5.1 Overview

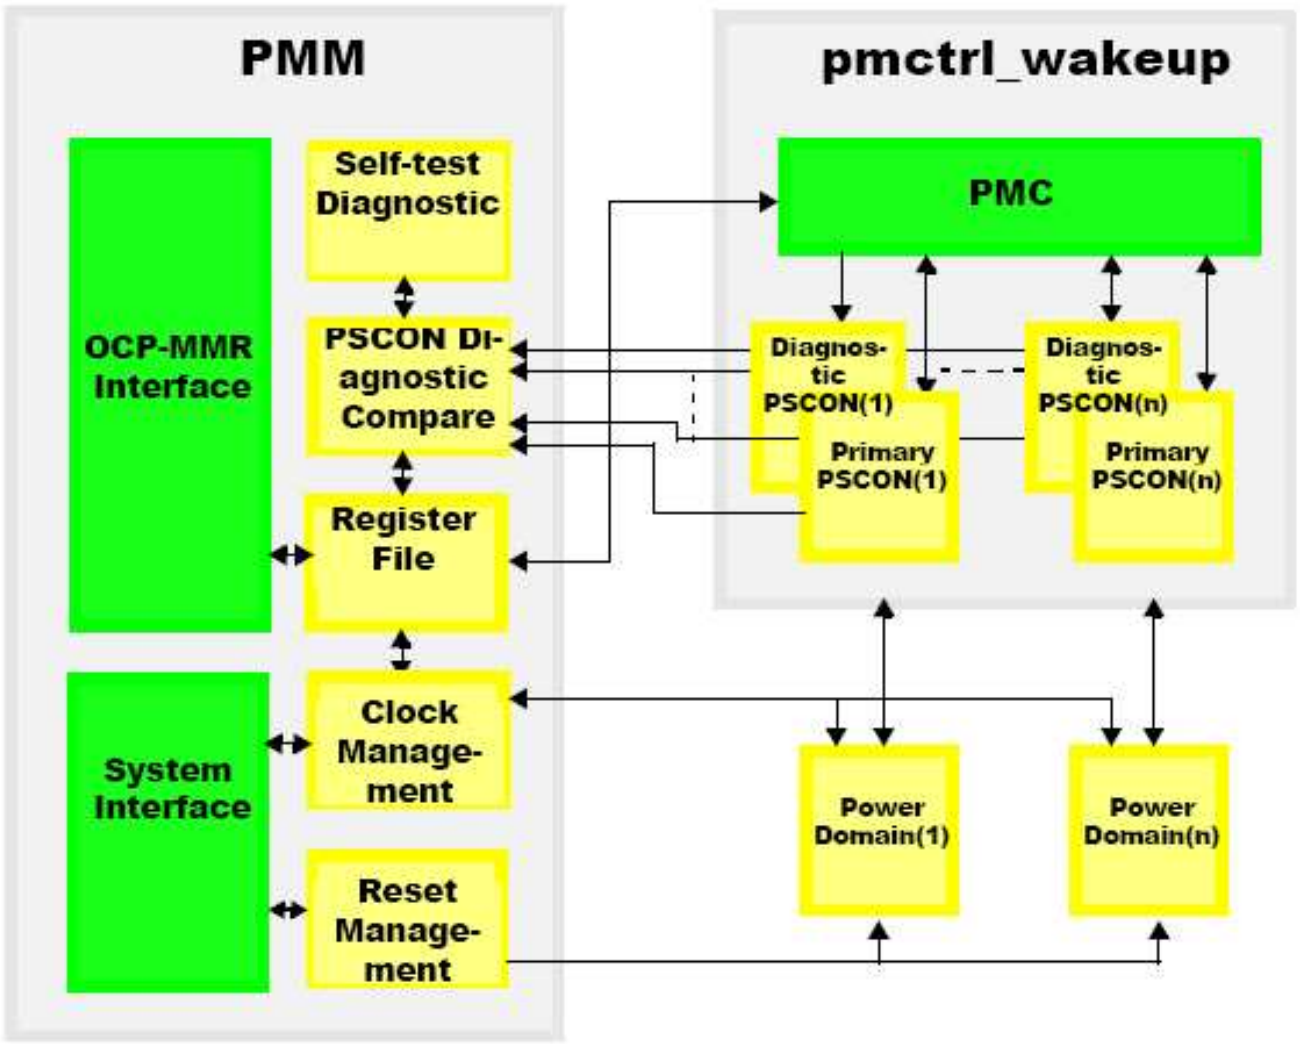
The microcontroller is part of the family of microcontrollers from Texas Instruments for safety-critical applications. Several functions are implemented on this microcontroller targeted towards varied applications. The core logic is divided into several domains that can be independently turned on or off based on the application's requirements. Turning off a domain has the effect to only turn off the clocks into the domain. Dynamic current is virtually reduced to zero. Leakage will remain the same as in this device no physical power switches are implemented to isolate a domain from its core supply.

This chapter describes the Power Management Module (PMM). The PMM provides memory-mapped registers that control the states of the supported power domains. The PMM includes interfaces to the Power Mode Controller (PMC) and the Power State Controller (PSCON). The PMC and PSCON control the power up/down sequence of each power domain.

5.1.1 Features

The main features of the PMM implemented on the microcontroller are:

- Supports 6 logic power domains: PD1, PD2, PD3, PD4, PD5 and PD6
- Allows configurable default states for each power domain
- Allows each power domain to be permanently disabled
- Manages the clocks for each power domain
- Manages the resets to each power domain
- Includes failsafe compare logic to continuously monitor the states of each power domain
- Supports diagnostic and self-test logic to validate failsafe compare logic



5.1.2 Block Diagram

PMM consists of several key components:

- Register interface – the PMM control registers are mapped to the device memory space and start at address 0xFFFF0000.
- System Interface – the PMM receives the clocks, resets, errors and all other control signals through this interface.
- PSCON Diagnostic Compare – this block compares the outputs of each primary PSCON and the respective diagnostic PSCON implemented for failsafe safety.
- Self-Test Diagnostic – this block contains the logic to place the PSCON diagnostic compare block in a self-test mode in order to test the failsafe feature.
- Clock management – the PMM provides independent clock gating and handshaking controls for each power domain and also generates the clock domains for each power domain.
- Reset Management – the PMM provides independent reset signals for each power domain.
- Power Mode Controller (PMC) – The PMC is a finite state machine that controls the power sequence from one power mode to another. A power mode is the states of all power domains at a given time.
- Power State Controller (PSCON) – The PSCON is a finite state machine that controls the power sequence of a power domain from one state to another. Each power domain is controlled by one dedicated PSCON.
- Power Domain – In this device, a power domain is a group of logic and/or memories which shares the common control inputs.

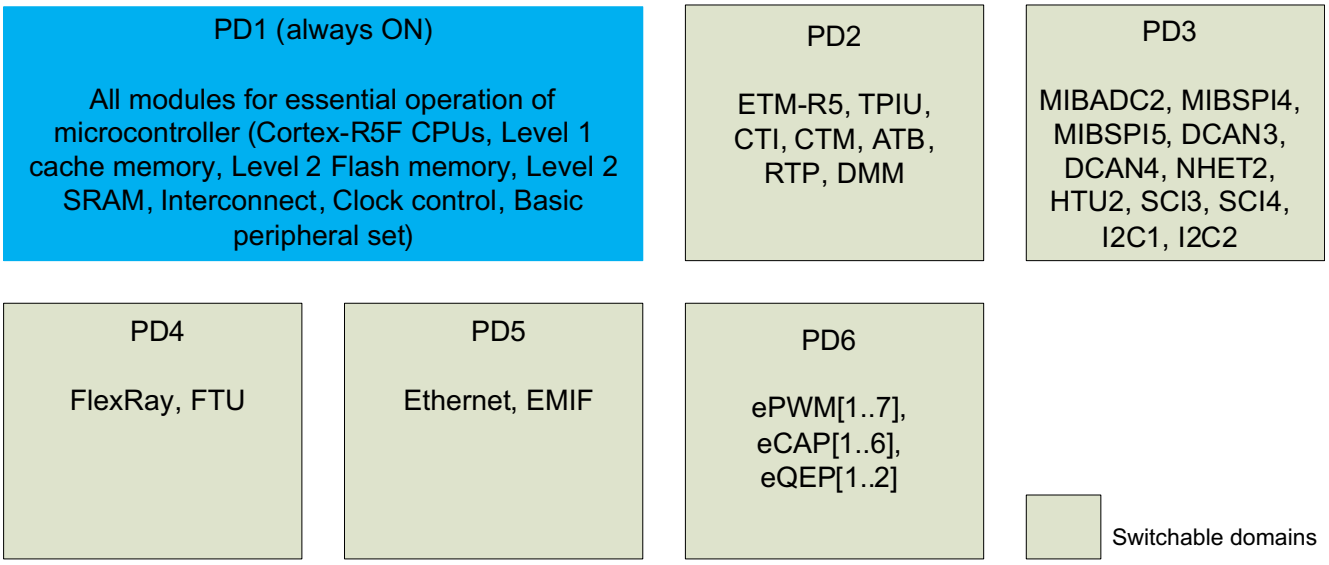
5.2 Power Domains

Figure 5-2 shows the core domains implemented on the microcontroller.



This device has 6 separate core power domains:

- PD1 is an always-ON domain and is not controlled by PMM. It contains the CPU as well as other principal modules and the interconnect required for operation of the microcontroller. This domain also includes the level 1 cache memory and the level 2 flash memory and SRAM. The PD1 can operate on its own even when all the other core power domains are turned off by the PMM. Note that all I/Os are in this always-ON domain as well.

Core power domains PD2 through PD6 are controlled by the PMM.

- PD2 contains logic related to debug, instrumentation and trace such as the Embedded Trace Macrocell (ETM-R5), RAM Trace Port (RTP), and Data Modification Module (DMM) components.
- PD3 contains some additional peripheral modules as an enhanced configuration over and above the peripheral set available in PD1. These include a second High-End Timer (N2HET2) with its dedicated transfer unit (HTU2), a second Analog-to-Digital Converter (ADC2), two Serial Communication Interfaces (SCI3 and SCI4), two Inter-Integrated Circuit controllers (I2C1 and I2C2), two Controller Area Network controller (DCAN3 and DCAN4), and two Multi-buffer Serial Peripheral Interface module (MibSPI4 and MibSPI5).
- PD4 contains the FlexRay controller and its dedicated transfer unit (FTU).
- PD5 contains the Ethernet controller (EMAC), the External Memory Interface (EMIF), as well as some components of the interconnect fabric required by these modules.
- PD6 contains seven Enhanced Pulse Width Modulation modules (ePWM), two Quadrature Encoder Pulse modules (nQEP), and six Enhanced Capture modules (eCAP).

Figure 5-2. Core Power Domains

5.3 PMM Operation

It is important to understand some fundamental concepts beforehand.

5.3.1 Power Domain State

Each core power domain can be in one of three states: Active, Idle, or Off.

In the ***Active*** state, a power domain is fully powered with normal supply voltage.

In the ***Idle*** state, all clocks to a power domain are turned off (driven low). The supply voltage is still maintained at the normal level.

In this device, the ***Off*** state is equivalent to the ***Idle*** state in terms of power saving. Users can still from a programmer's model perspective put a power domain into the Off state as if the power domain can be physically turned off.

NOTE: This device does not implement power switches to physically isolate the power domain from its power supply. Putting a power domain into the Off state has no effect to remove leakage power. Power domains in this device are group of modules surrounded by the isolation cells. Isolation cells are placed at the outputs of the power domains. When a power domain is put into Off state, the isolation cells are enabled and force inactive states on the output signals. PMM and the PSCONs do not know the physical implementation of the power domains. The logic to control the transition from one power state to another will behave the same as if the power domains can be physically turned off.

5.3.2 Default Power Domain State

The default state of each power domain, except for PD1, is controlled by TI during production testing via programmation of individual bits within the reset configuration word in the TI-OTP sector of flash bank 0. This allows each power domain to default to either the active state or the off state.

5.3.3 Disabling a Power Domain Permanently

TI can also permanently disable any power domain, except for PD1. This is also controlled by programmation of individual bits within the reset configuration word in the TI-OTP sector of flash bank 0.

5.3.4 Changing Power Domain State

A domain can only change state when commanded by the application. Each domain has an associated 4-bit key to define the intended power state. When the correct key is programmed, the PMM initiates the sequence to transition that domain to the commanded state.

5.3.4.1 Turning a Power Domain Off

It is necessary to turn off all clocks going to a power domain before that domain can be powered down. PMM contains the hardware interlocks to handle this. Each power domain has an associated memory-mapped register which allows the application to turn off clocks to that power domain.

Steps to power down a domain with logic – PD2, PD3, PD4, PD5, PD6:

1. Write to the PDCLK_DISx register to disable all clocks to the power domain.
2. Write 0xA to the LOGICPDPWRCTRL0 register to power down the domain.
3. Poll for LOGICPDPWRSTATx to become “00”. The power domain is now powered down.

Copyright © 2018, Texas Instruments Incorporated

5.3.4.2 Turning a Power Domain On

A power domain can be turned on by writing the correct key to the LOGICPDON register. PMM will automatically restart the clocks to the power domain once the ***Active*** power state is restored if the "automatic clock enable upon wake up" option is selected. If this option is not selected, the application can turn on clocks to the power domain by clearing the PDCLK_DIS register manually. The application must poll the DOMAINISON register to ensure that the power has been fully restored before enabling the clocks.

5.3.5 Reset Management

PMM handles the reset sequence for each power domain. When a power domain is turned on from an off state, the PMM will reset the power domain to ensure that all logic begins in its default reset state.

PMM generates nPORRST (power-on reset), nRST (system reset), nPRST (peripheral reset), and nTRST (test / debug logic reset) for each domain.

5.3.6 Diagnostic Power State Controller (PSCON)

Each power domain state is controlled by a primary PSCON. There is a second PSCON as well for each power domain. This is the diagnostic PSCON. All power management inputs to a power domain are controlled only by the primary PSCON. All power management outputs from the power domain are fed back to both the primary and the diagnostic PSCON.

The PMM commands both the PSCON identically so that they are always in a lock-step operating mode. A dedicated compare unit checks the outputs of the two PSCON modules on every cycle.

5.3.7 PSCON Compare Block

The diagnostic compare block can operate in one of four modes.

5.3.7.1 Lock-Step Mode

This is the default mode of operation of the PSCON compare block. The PSCON diagnostic compare block compares the outputs from the two PSCONs on every cycle. Any mismatch in the PSCON outputs is indicated as a PSCON compare error. This error signal is mapped to the Error Signaling Module's (ESM) Group1 channel 38. The application can define the response to this error.

5.3.7.2 Self-Test Mode

A self-test mechanism is provided to check the PSCON compare logic for faults. The compare error signal output is disabled in self-test mode. The PSCON diagnostic compare block generates two types of patterns during self-test mode: compare match test followed by compare mismatch test. During the self-test, each test pattern is applied on both PSCON signal ports of the PSCON diagnostic compare block and then is clocked for one cycle. The duration of the self-test is 24 cycles. Any detected fault is indicated as a self-test error, mapped to ESM group1 channel 39. If no fault is detected, the self-test complete flag is set.

The application can poll for this flag to be set and then switch the mode of the PSCON compare block back to lock-step mode by writing to the mode key register.

NOTE: PSCON operation when compare block is in self-test mode

When the PSCON compare block is in its self-test mode, both PSCONs continue to function normally. However, there is no comparison done on the PSCON outputs.

Compare match test:

An identical vector is applied to both input ports at the same time, thereby expecting a compare match. If the compare unit produces a mismatch then the self-test error flag is set and the self-test error signal is generated. The compare match test is terminated if a compare mismatch is detected. The compare match test takes 4 cycles to complete when the test passes.

Copyright © 2018, Texas Instruments Incorporated

Compare mismatch test:

A vector with all 1's is applied to the PSCON diagnostic compare block's primary input port and the same input is also applied to the secondary input port but with one bit flipped starting from bit position 0. The unequal vectors should cause the PSCON diagnostic compare block to generate a compare mismatch at bit position 0. In case a mismatch is not detected, a self-test error is indicated. This compare mismatch test algorithm is repeated until every single bit position is verified on both PSCON signal ports.

5.3.7.3 Error-Forcing Mode

This mode is designed specifically to ensure that the error signal output from the PSCON compare block is not stuck inactive. In this mode, a test pattern is applied to the PSCON related inputs of the compare logic to force an error. The application can clear the flag for ESM group1 channel 38 once the error is flagged. If the ESM group1 channel 38 flag does not get set, this indicates that the PSCON compare error signal is stuck inactive and cannot be relied upon to detect a PSCON mismatch.

5.3.7.4 Self-Test Error-Forcing Mode

In this mode, an error is forced so that the self-test error output from the PSCON compare block is activated. The application can clear the flag for ESM group1 channel 39 once the error is flagged. If the ESM group1 channel 39 flag does not get set, this indicates that the PSCON compare block self-test error signal is stuck inactive and there is no self-test mechanism available for the PSCON compare block.

5.3.7.5 PMM Operation During CPU Halt Debug Mode

No compare errors are generated when the CPU is halted in debug mode, regardless of the mode of the diagnostic compare block. No status flags are updated in this mode. Normal operation of the compare block is resumed once the CPU exits the debug mode.

5.4 PMM Registers

Table 5-1 lists the control registers in the PMM module. The registers support 8-, 16-, and 32-bit accesses. The address offset is specified from the base address of FFFF 0000h. Any access to an unimplemented location within the PMM register frame will generate a bus error that results in an Abort exception.

5.4.10 Logic Power Domain PD6 Power Status Register (LOGICPDPWRSTAT4)

This is a read-only register. All writes are ignored.

The default values of the control fields are determined by the device reset configuration word stored in the TI-OTP region of flash bank 0.

I/O Multiplexing and Control Module (IOMM)

This chapter describes the I/O Multiplexing and Control Module (IOMM).

Topic **Page**

6.1 Overview 302
6.2 Main Features of I/O Multiplexing Module (IOMM) 302
6.3 Control of Multiplexed Outputs 302
6.4 Control of Multiplexed Inputs 303
6.5 Control of Special Multiplexed Options 312
6.6 Safety Features 327
6.7 IOMM Registers 328

Copyright © 2018, Texas Instruments Incorporated

6.1 Overview

This chapter describes the overall features of the module that control the I/O multiplexing on the device. The mapping of control registers to multiplexing options is specified in Section 6.7.13.

6.2 Main Features of I/O Multiplexing Module (IOMM)

The IOMM contains memory-mapped registers (MMR) that control device-specific multiplexed functions. The safety and diagnostic features of the IOMM are:

- Kicker mechanism to protect the MMRs from accidental writes
- Error indication for access violations

6.3 Control of Multiplexed Outputs

The signal multiplexing controlled by each memory-mapped control register (PINMMRn) is described in Table 6-1. Each byte in the PINMMRs control the functionality output on a single terminal. Consider the following example for the PINMMR9 control register.

Figure 6-1. PINMMR9 Control Register [Address Offset = 134h]

31	27	26	25	24

Reserved		ECLK2	EMIF_CLK	Reserved
R/WP-0		R/WP-0	R/WP-0	R/WP-1

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

- Consider the multiplexing controlled by PINMMR9[23–16]. These bits control the multiplexing between the EMIF_nCS[0], RTP_DATA[15] and N2HET2[7] on the ball N17 of the 337BGA package for this device. The default function on the N17 ball is EMIF_nCS[0]. This is dictated by bit 16 of the PINMMR9 register being set.
- If the application wants to use N17 as an N2HET2[7] signal, then bit 16 of PINMMR9 must be cleared and bit 18 must be set. Likewise, if RTP_DATA[15] is to be brought out, then bit 16 of PINMMR9 must be cleared and bit 17 must be set.
- Each feature of the output function is determined by the function selected to be output on a terminal.

  For example, the ball N17 on the 337BGA package is driven by an output buffer with an 8mA drive strength. This output buffer has the following signals: A (signal to be output) and GZ (output enable). Each of these signals is an output of a multiplexor that allows the selected function to control all available features of the output buffer. Some output buffers may have additional options as output strength, slew rate, and so on. This options are also controlled by the multiplexor output.
- The PINMMR control registers are used to implement a one-hot encoding scheme for selecting the multiplexed function.
  - For example, for the N17 ball on the 337BGA package for this device only one out of bit 16, 17 or bit 18 must be set.
  - If the application clears bits 16, 17 and 18, then the default function, EMIF_nCS[0], will be selected for output on N17.
  - If the application sets 16, 17 and 18, then the default function will be selected for output on N17.

Copyright © 2018, Texas Instruments Incorporated

– If the application sets one or more reserved bit(s) within the byte 23–16, then the default function will be selected for output on N17.

Figure 6-2 shows the multiplexing between the output functions for the N17 ball. This terminal uses an 8mA output buffer.

Figure 6-2. Output Multiplexing Example

In Table 6-1, the column "Selection Bit" contains a value of type x[y] that corresponds to the control register PINMMRx, bit y. It indicates the multiplexing control register and the bit that must be set in order to select the corresponding functionality to be brought out to the terminal. If an un-implemented alternate function is selected where a physical pin is attached, the default function is used. When a PINMMRx register is completely reserved, none of its 8-bit fields are attached to any physical pin.

6.4 Control of Multiplexed Inputs

In this microcontroller, some signals are connected to more than one terminal, so that the inputs for these signals can come from either of these terminals. A multiplexor is implemented to let the application choose the terminal that will be used for providing the input signal from among the available options. The input path selection is done based on two bits in the PINMMR control register as shown in Table 6-2.

- The input to a module comes from the **Default Terminal** when the associated bit in the **Terminal 1 Input Multiplex Control** column is set and the bit in the **Terminal 2 Input Multiplex Control** column is clear. By default, the bit in the **Terminal 1 Input Multiplex Control** column is set after reset.
- The input to a module comes from the **Alternate Terminal** when the associated bit in the **Terminal 2 Input Multiplex Control** column is set and the bit in the **Terminal 1 Input Multiplex Control** column is clear.

NOTE: If multiple bits or no bit are selected in the Input Multiplex Control, the Default Function will then be selected.

Some signals, like eCAPx and eQEPx, are by default mapped to an unavailable ball on the 337ZWT package. The alternate terminals have to be used, in this case, in order to use these signals.

NOTE: Inputs are broadcast to all multiplexed functions

The input signals are broadcast to all modules hooked up to a terminal. The application must ensure that modules that are not being used in the application do not react to a change on their input functions. For example, a GIO signal toggle can trigger an interrupt request, when the application actually is using the function multiplexed with this GIO signal.

6.5.1 Control of SDRAM Clock (EMIF_CLK)

As shown in Table 6-1, PINMMR9[0] is set by default. This blocks the EMIF SDRAM clock signal (EMIF_CLK) from being output from the microcontroller. If the EMIF is used to connect to an external SDRAM module, then the application must enable the SDRAM clock output by clearing the PINMMR9[0] bit and set the PINMMR9[1].

6.5.2 Control for other EMIF Outputs

There are some EMIF signals (EMIF_ADDR[00], EMIF_ADDR[01], EMIF_ADDR[06], EMIF_ADDR[07], EMIF_ADDR[08], EMIF_BA[1], EMIF_nCS[0], EMIF_nCS[3]), that are multiplexed with N2HET2 signals. For applications that require the use of these N2HET2 signals, it is inconvenient if the EMIF starts driving these address and control signals as output after reset is released and before the application can configure the I/O Multiplexing Module registers. Therefore, these EMIF signals are blocked from being output by default when PINMMR174[8]=1 and PINMMR174[9]=0. In this condition, these EMIF/N2HET2 terminals are configured as inputs and pulled down. An application that requires the EMIF functionality must set PINMMR174[8]=0 and PINMMR174[9]=1. This causes the EMIF address and control signals to then be output on the EMIF/N2HET2 terminals when the EMIF functionality is selected via the IOMM output multiplexing control registers.

6.5.3 Control of Ethernet Controller Mode

PINMMR160[24] is set by default. This bit is used to enable the RMII (Reduced Media Independent Interface of the Ethernet controller). If the application desires to use the MII (Media Independent Interface of the Ethernet controller), then the PINMMR160[24] must be cleared.

6.5.4 Control of ADC Trigger Events

The microcontrollers contain two Analog-to-Digital Converter modules: ADC1 and ADC2. The ADC conversions can be started using a rising or falling or both edges as the trigger event. Both the ADC modules support up to eight event trigger inputs. There are two sets of these 8 inputs for each ADC. The option for each of these 8 inputs are controlled by registers in the I/O multiplexing module as shown in Table 6-4 and Table 6-5.

Table 6-4. ADC1 Trigger Event Selection

Group Source Select, G1SRC, G2SRC or EVSRC	Event #	PINMMR161[0]	PINMMR161[1]	Control Option A	Control Option B	Trigger Source

6.5.5 Control for ADC Event Trigger Signal Generation from ePWMx Modules

This microcontroller implements 7 ePWM modules, see Figure 6-4. Each of these modules generate two outputs, SOCA (Start Of Conversion) and SOCB, for use in triggering the on-chip ADC modules. Registers from the I/O multiplexing module are used to control the logic for generation of the ePWM_A1, ePWM_A2, ePWM_AB, and ePWM_B signals from these ePWMx_SOCA and ePWMx_SOCB signals.

Copyright © 2018, Texas Instruments Incorporated

Figure 6-4. ADC Trigger Event Signal Generation from ePWMx

Copyright © 2018, Texas Instruments Incorporated

The logic equations for the 4 outputs from the combinational logic shown in Figure 6-4 are:

- B = SOC1B or SOC2B or SOC3B or SOC4B or SOC5B or SOC6B or SOC7B
- A1 = [SOC1A and not(SOC1A_SEL)] or
  [SOC2A and not(SOC2A_SEL)] or
  [SOC3A and not(SOC3A_SEL)] or
  [SOC4A and not(SOC4A_SEL)] or
  [SOC5A and not(SOC5A_SEL)] or
  [SOC6A and not(SOC6A_SEL)] or
  [SOC7A and not(SOC7A_SEL)] or
- A2 = [SOC1A and SOC1A_SEL] or
  [SOC2A and SOC2A_SEL] or
  [SOC3A and SOC3A_SEL] or
  [SOC4A and SOC4A_SEL] or
  [SOC5A and SOC5A_SEL] or
  [SOC6A and SOC6A_SEL] or
  [SOC7A and SOC7A_SEL] or
- AB = B or A2

The SOCxA_SEL signals used in the above logic equations are generated using registers in the I/O multiplexing module.

- PINMMR164[0] defines the value of SOC1A_SEL. This bit is set by default and can be cleared by the application.
- PINMMR164[8] defines the value of SOC2A_SEL. This bit is set by default and can be cleared by the application.
- PINMMR164[16] defines the value of SOC3A_SEL. This bit is set by default and can be cleared by the application.
- PINMMR164[24] defines the value of SOC4A_SEL. This bit is set by default and can be cleared by the application.
- PINMMR165[0] defines the value of SOC5A_SEL. This bit is set by default and can be cleared by the application.
- PINMMR165[8] defines the value of SOC6A_SEL. This bit is set by default and can be cleared by the application.
- PINMMR165[16] defines the value of SOC7A_SEL. This bit is set by default and can be cleared by the application.

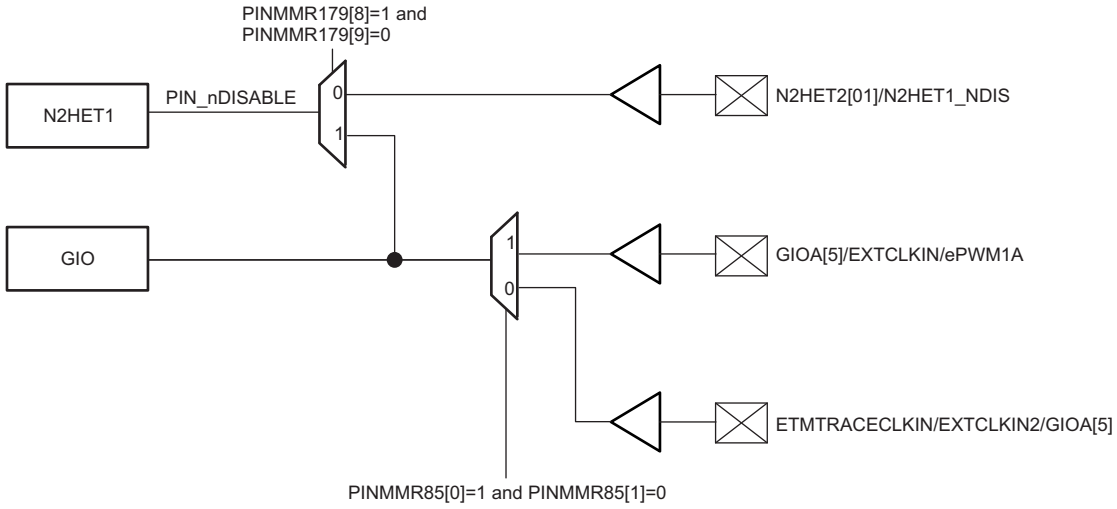
6.5.6 Control for Generating Interrupt Upon External Fault Indication to N2HETx



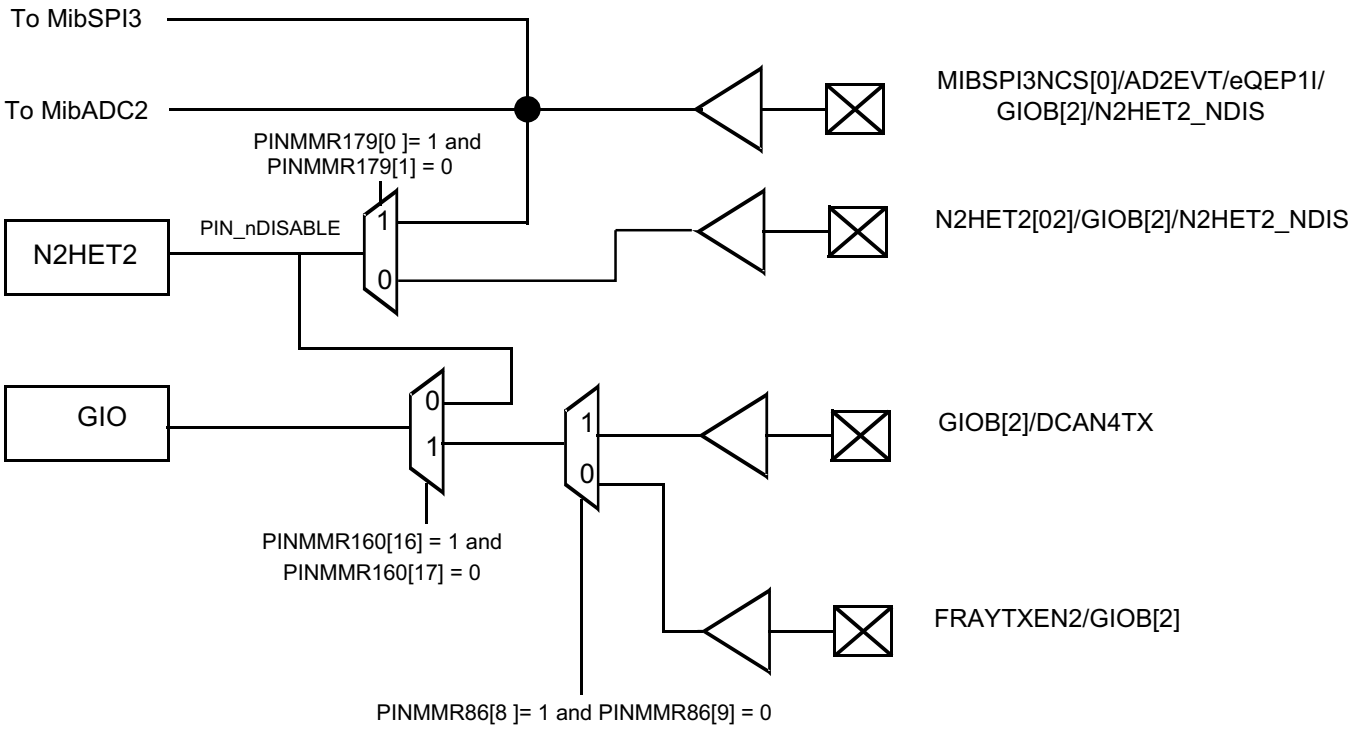
The N2HET module on this microcontroller allows the application to selectively disable any PWM output from the N2HET module whenever a fault condition is indicated to the N2HET. This fault condition is input to the N2HET module via the PIN_nDISABLE input signal. It is important for the CPU to be notified with an interrupt whenever this fault condition is indicated to the N2HET module.

The PIN_nDISABLE signal for the N2HET1 module can come from two different paths at either the GIOA[5] terminals or the N2HET2[01] terminal. By default with PINMMR179[8]=1 and PINMMR179[9]=0 the GIOA[5] / EXTCLKIN / ePWM1A terminal is selected as the input for signaling the fault condition. Setting PINMMR179[8]=0 and PINMMR179[9]=1 will select the terminal N2HET2[01] / N2HET1_NDIS for signaling the fault condition.

Note that there are two terminals from which to choose the GIOA[5] signal since GIOA[5] is available in two different terminals. By default with PINMMR85[0]=1 and PINMMR85[1]=0 the terminal shared by GIOA[5] / EXTCLKIN / ePWM1A is selected. Setting PINMMR85[0]=0 and PINMMR85[1]=1 will select the terminal shared by ETMTRACECLKIN / EXTCLKIN2 / GIOA[5]. When GIOA[5] is chosen to signal the fault condition it can also be an interrupt to the CPU if the application enables the interrupt generation whenever the GIOA[5] terminal is driven low. Figure 6-5 illustrates the multiplexing scheme.

NOTE: The default settings will choose GIOA[5] / EXTCLKIN / ePWM1A terminal for signaling the fault condition to the N2HET1 and this will be compatible to other TMS570LSxx family of microcontrollers which have this available feature.

Figure 6-5. GIOA[5] and N2HET1_NDIS Input Multiplexing Scheme



Copyright © 2018, Texas Instruments Incorporated

The PIN_nDISABLE signal for the N2HET2 module can also come from two different paths at either the MIBSPI3NCS[0] / AD2EVT / eQEP1I / GIOB[2] / N2HET2_NDIS terminal or the N2HET2[02] / GIOB[2] / N2HET2_NDIS terminal. By default with PINMMR179[0]=1 and PINMMR179[1]=0, the MIBSPI3NCS[0] / AD2EVT / eQEP1I /GIOB[2] / N2HET2_NDIS terminal is selected as the input for signaling the fault condition. Setting PINMMR179[0]=0 and PINMMR179[1]=1 will select the N2HET2[02] / GIOB[2] / N2HET2_NDIS terminal for signaling the fault condition. By default with PINMMR160[16]=1 and PINMMR160[17]=0, these signals do not offer the capability of generating an interrupt to the GIO module when they are driven low. Therefore, the input from this terminal can optionally be connected to the GIOB[2] input. This connection is enabled by setting PINMMR160[0]=0 and PINMMR160[1]=1.

Note that the GIO module has four sources from which to choose the GIOB[2] signal. By default with PINMMR86[8]=1 and PINMMR86[9]=0, the GIOB[2] / DCAN4TX terminal is selected that is defined in Table 6-2, see register at address FFFF_1E68h. By setting PINMMR86[8]=0 and PINMMR86[9]=1, the terminal shared by FRAYTXEN2 and GIOB[2] is selected. When either one of these two terminals is selected, it is not possible to use GIO module to cause an interrupt to the CPU when a fault condition is detected. To cause an interrupt to the GIO using GIOB[2] or N2HET2_NDIS signal, the PINMMR160[16] must be clear and PINMMR160[17] must be set while either MibSPI3NCS[0] / AD2EVT /GIOB[2] terminal or the N2HET2[02] / N2HET2_NDIS terminal is connected to the external monitor circuit. Figure 6-6 illustrates the multiplexing scheme.

Figure 6-6. GIOB[2] and N2HET2_NDIS Input Multiplexing Scheme

NOTE: The default settings will choose MIBSPI3NCS[0] / AD2EVT / GIOB[2] terminal for signaling the fault condition to the N2HET2 and this will be compatible to other TMS570LSxx family of microcontrollers which have this available feature.

6.5.7 Control for Synchronizing Time Bases for All ePWMx Modules

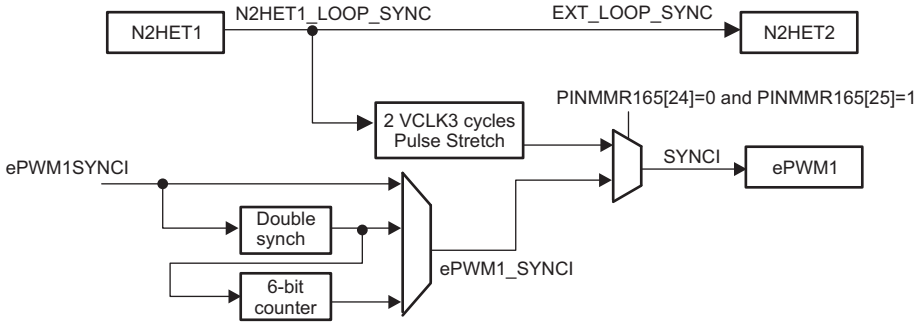
The ePWMx modules implement a mechanism that allows their time bases to be synchronized. This is done by using a signal called TBCLKSYNC, which is a common input to all the ePWMx modules. This TBCLKSYNC is generated by a register bit in the I/O multiplexing module. PINMMR166[1] is the TBCLKSYNC signal. This bit is cleared (0) by default.

When TBCLKSYNC = 0, the time-base clock of all ePWMx modules is stopped. This is the default condition.

When TBCLKSYNC = 1, the time-base clocks of all ePWMx modules are started aligned to the rising edge of the TBCLKSYNC signal.

The correct procedure for enabling and synchronizing the time-base clocks of all the ePWMx modules is:

1. Enable the clocks to the desired individual ePWMx modules if they have been disabled
2. Set TBCLKSYNC = 0. This will stop the time-base clocks of any enabled ePWMx module.
3. Configure the time-base clock prescaler values and desired ePWM modes.
4. Set TBCLKSYNC = 1.



6.5.8 Control for Synchronizing all ePWMx Modules to N2HET1 Module Time-Base

Some applications require a synchronized time base for all PWM signals generated by the microcontroller. The N2HET1 module uses a time base that is created by configuring the high-resolution and loop-resolution prescalers in the N2HET1 module control registers. The N2HET1 module outputs the loop-resolution clock signal (N2HET1_LOOP_SYNC) so that other timer modules on the microcontroller can use it to synchronize their time bases to the N2HET1 loop-resolution clock.

There is a dedicated connection between the N2HET1 and N2HET2 modules, which allows the N2HET2 to use the N2HET1_LOOP_SYNC signal to synchronize its own time base to that of N2HET1.

The seven ePWMx modules can also optionally use the N2HET1_LOOP_SYNC for their time-base synchronization using a specially designed scheme.

Figure 6-7. Synchronizing ePWMx Modules to N2HET1 Time-Base

Copyright © 2018, Texas Instruments Incorporated

PINMMR165[24] and PINMMR165[25] are used to select between the ePWM1_SYNCI and the stretched N2HET1_LOOP_SYNC signals.

- If PINMMR165[24] = 1 and PINMMR165[25] = 0, the SYNCI input to the ePWM1 comes from the ePWM1_SYNCI which is an output from a multiplexor. This is the default connection. There are also three possible selections from which to choose the ePWM1_SYNC1.
  - When PINMMR173[8] = 1, the EPWM1SYNCI terminal is connected directly to the ePWM1 module's SYNCI port. This is the default connection.
  - When PINMMR173[8] = 0, PINMMR173[9] = 1, and PINMMR173[10] = 0, the EPWM1SYNCI terminal is double-synchronized using VCLK3 and then connected to the ePWM1 module's SYNCI port.
  - When PINMMR173[8] = 0, PINMMR173[9] = 0, and PINMMR173[10] = 1, the EPWM1SYNCI terminal is double-synchronized using VCLK3, qualified through a 6-cycle counter using VCLK3 and then connected to the ePWM1 module's SYNCI port.
- If PINMMR165[24]=0 and PINMMR165[25]=1, the SYNCI input to the ePWM1 comes from the pulse-stretched N2HET1_LOO_SYNC signal.

6.5.9 Control for Input Connections to ePWMx Modules

The ePWMx modules take the following signals as input:

- ePWM1_SYNCI: external time-base input to the ePWMx
- nTZ1 through nTZ6: trip-zone inputs to the ePWMx

Of the six trip-zone inputs, three are input from device terminals while the other three are connected to internal error events. Registers from the I/O multiplexing module are used to control various aspects of these input connections to the ePWMx modules.

Table 6-6. Controls for ePWMx Inputs

Input Signal	Control for Asynchronous Input (default connection)	Control for Double-VCLK3-Synchronized Input	Control for Double-VCLK3-Synchronized and 6-VCLK3-Filtered Input
nTZ1	PINMMR172[16] = 1	PINMMR172[16] = 0 PINMMR172[17] = 1	PINMMR172[17:16] = "00" PINMMR172[18] = 1
nTZ2	PINMMR172[24] = 1	PINMMR172[24] = 0 PINMMR172[25] = 1	PINMMR172[25:24] = "00" PINMMR172[26] = 1
nTZ3	PINMMR173[0] = 1	PINMMR173[0] = 0 PINMMR173[1] = 1	PINMMR173[1:0] = "00" PINMMR173[2] = 1
ePWM1_SYNCI	PINMMR173[8] = 1	PINMMR173[8] = 0 PINMMR173[9] = 1	PINMMR173[9:8] = "00" PINMMR173[10] = 1

Copyright © 2018, Texas Instruments Incorporated

Of the three internal error events for the trip-zone inputs, nTZ4 is connected to the eQEPx error output signal. There are two eQEP modules on this microcontroller, and registers in the I/O multiplexing module are used to allow a flexible scheme for the connection between the eQEPx error signal and the nTZ4 inputs of the ePWMx modules.

Table 6-7. Controls for eQEPx_ERROR Connection to ePWMx nTZ4 Inputs

ePWMx Module	Control for nTZ4 = not(eQEP1ERR or eQEP2ERR) (default connection)	Control for nTZ4 = not(eQEP1ERR)	Control for nTZ4 = not(eQEP2ERR)
ePWM1	PINMMR167[0] = 1	PINMMR167[0] = 0 PINMMR167[1] = 1	PINMMR167[1:0] = "00" PINMMR167[2] = 1
ePWM2	PINMMR167[8] = 1	PINMMR167[8] = 0 PINMMR167[9] = 1	PINMMR167[9:8] = "00" PINMMR167[10] = 1
ePWM3	PINMMR167[16] = 1	PINMMR167[16] = 0 PINMMR167[17] = 1	PINMMR167[17:16] = "00" PINMMR167[18] = 1
ePWM4	PINMMR167[24] = 1	PINMMR167[24] = 0 PINMMR167[25] = 1	PINMMR167[25:24] = "00" PINMMR167[26] = 1
ePWM5	PINMMR168[0] = 1	PINMMR168[0] = 0 PINMMR168[1] = 1	PINMMR168[1:0] = "00" PINMMR168[2] = 1
ePWM6	PINMMR168[8] = 1	PINMMR168[8] = 0 PINMMR168[9] = 1	PINMMR168[9:8] = "00" PINMMR168[10] = 1
ePWM7	PINMMR168[16] = 1	PINMMR168[16] = 0 PINMMR168[17] = 1	PINMMR168[17:16] = "00" PINMMR168[18] = 1

6.5.10 Control for Input Connections to eCAPx Modules

Each eCAPx module has a single input from the device terminals. This input can be connected to the eCAPx module in one of two ways:

1. Double-synchronized using VCLK3
2. Double-synchronized using VCLK3 and then filtered through a 6-VCLK3-cycle counter

Registers in the I/O multiplexing module are used to control these input connections for each eCAPx module.

Table 6-8. Controls for eCAPx Inputs

eCAPx Input	Control for Double-VCLK3-Synchronized Input (default connection)	Control for Double-VCLK3-Synchronized and 6-VCLK3-Filtered Input
eCAP1	PINMMR169[0] = 0	PINMMR169[0] = 0 PINMMR169[1] = 1

6.5.11 Control for Input Connections to eQEPx Modules

Each eQEPx module has four inputs from the device terminals. These inputs can be connected to the eQEPx module in one of two ways:

1. Double-synchronized using VCLK3
2. Double-synchronized using VCLK3 and then filtered through a 6-VCLK3-cycle counter

Registers in the I/O multiplexing module are used to control these input connections for each eQEPx module.

Table 6-9. Controls for eQEPx Inputs

eQEPx Input	Control for Double-VCLK3-Synchronized Input (default connection)	Control for Double-VCLK3-Synchronized and 6-VCLK3-Filtered Input

6.5.11.1 nERROR and nERROR1 Input Multiplexing

There are two ESM modules in this microcontroller. When the microcontroller is in lockstep mode, only ESM1 is active.

By default, the ESM1 Error Pin Status Register (ESMEPSR) samples the nERROR pin input. The default is achieved with PINMMR174[16] = 1. By setting PINMMR174[16] = 0, the ESM1 Error Pin Status register will sample from the nERROR1 pin instead as illustrated in Figure 6-8.

Figure 6-8. nERROR and nERROR1 Input Multiplexing

6.5.12 Selecting GIO Port for External DMA Request

GIOA and GIOB ports can be used to generate external DMA request. See the datasheet for the DMA request mapping. The polarity of the GIO pin to trigger a DMA request can be selected inside the DMA module. In order to use GIO pin as an external DMA request input, the corresponding pin must be first selected by the application. By default, it is unselected. See Figure 6-9 for illustration. In this illustration, the DMQREQ[32] input to the DMA module can come from several different sources including GIOA[0]. By default with PINMMR175[0] = 1, all other sources except GIOA[0] can be selected to generate a DMA request. Care must be taken by the application that only one source is active while other sources are inactive from their respective modules. When PINMMR175[0] = 0, only GIOA[0] is selected to generate the DMA request.

Figure 6-9. Using GIO Pin for External DMA Request

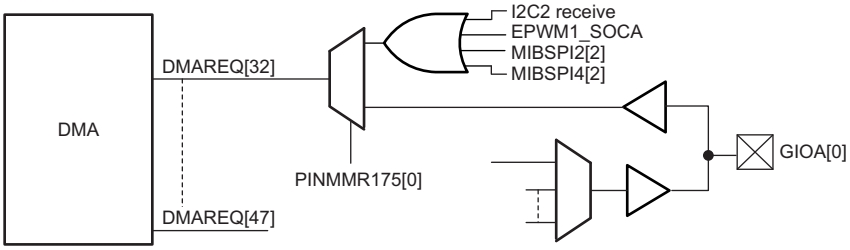

Table 6-10. GIO DMA Request Select Bit Mapping

GIO Pin	GIO DMA Request Select Bit	Bit Value to Select GIO
GIOA[0]	PINMMR175[0]	0
GIOA[1]	PINMMR175[8]	0
GIOA[2]	PINMMR175[16]	0
GIOA[3]	PINMMR175[24]	0
GIOA[4]	PINMMR176[0]	0
GIOA[5]	PINMMR176[8]	0
GIOA[6]	PINMMR176[16]	0
GIOA[7]	PINMMR176[24]	0
GIOB[0]	PINMMR177[0]	0
GIOB[1]	PINMMR177[8]	0

6.5.13 Temperature Sensor Selection

There are three instances of temperature sensors in this microcontroller. The measured temperatures are analog signals. These analog signals are connected to the on-chip ADCs for conversion. Before the temperature sensors can be used, they must be enabled. By default, they are disabled with PINMMR174[24] = 1. To enable the temperature sensors, PINMMR174[24] must be cleared to 0.

- Temperature sensor 1's output is multiplexed with AD1IN[31].
- Temperature sensor 2's output is multiplexed with AD2IN[31].
- Temperature sensor 3's output is multiplexed with AD2IN[30].

NOTE: To use AD1IN[31], PINMMR174[24] must be cleared to 0.

Table 6-11. Temperature Sensor Selection

Decode[1]	Select
AD1CHNSEL(31) = 1 PINMMR173(16) = 0 PinMMR173(17) = 1	Temp Sensor 1
AD1CHNSEL(31) = 1 PINMMR173(16) =1 PinMMR173(17) = 0	AD1IN[31]
AD2CHNSEL(31) = 1 PINMMR173(24) =0 PINMMR173(25) = 1	Temp Sensor 2
AD2CHNSEL(31) = 1 PINMMR173(24) =1 PINMMR173(25) = 0	AD2IN[31]
AD2CHNSEL(30) = 1 PINMMR174(0) =0 PINMMR174(1) = 1	Temp Sensor 3
AD2CHNSEL(30) = 1 PINMMR174(0) =1 PINMMR174(1) = 0	AD2IN[30]

(1) AD1CHNSEL is configured inside the MibADC1 Wrapper. AD2CHNSEL is configured inside the MibADC2 Wrapper.

6.6 Safety Features

The IOMM supports certain safety functions that are designed to prevent unintentional changes to the I/O multiplexing configuration. These are described in the following sections.

6.6.1 Locking Mechanism for Memory-Mapped Registers

The IOMM contains a mechanism to prevent any spurious writes from changing any of the PINMMR values. The PINMMRs are locked by default and after any system reset. None of the IOMM registers can be written under this condition. The application can read any of the IOMM registers regardless of the state of the locking mechanism.

- ***Enabling Write Access to the PINMMRs***

To enable write access to the PINMMRs, the CPU must write 0x83e70b13 to the kick0 register followed by a write of 0x95a4f1e0 to the kick1 register.

- ***Disabling Write Access to the PINMMRs***

It is recommended to disable write access to the PINMMRs once the I/O multiplexing configuration is completed. This can be done by:

- writing any other data value to either of the kick registers, or
- restarting the unlock sequence by writing 0x83e70b13 to the kick0 register

NOTE: No Error On Write to Locked PINMMRs

There is no error response on any write accesses to the PINMMRs when write access is disabled. None of the PINMMRs change state due to this write.

6.6.2 Error Conditions

The IOMM generates one error signal that is mapped to the Error Signaling Module's Group 1, channel 37. This error signal is generated under either of the following two conditions:

- Address Error – occurs when there is a read or a write access to an un-implemented memory location within the IOMM register frame.
- Protection Error – occurs when the CPU writes to an IOMM register while not in a privileged mode of operation.

6.7.12 PINMMRnn: Output Pin Multiplexing Control Registers

These registers control the output multiplexing of the functionality available on each pad on the microcontroller. There are 38 such registers – PINMMR0 through PINMMR37. Each 8-bit field of a PINMMR register controls the functionality of a single ball/pin. The mapping between the PINMMRx control registers and the functionality selected on a given terminal is defined in Table 6-1.

F021 Level 2 Flash Module Controller (L2FMC)

The Flash electrically-erasable programmable read-only memory module is a type of nonvolatile memory that has fast read access times and is able to be reprogrammed in the field or in the application. It also allows remapping of the Flash to RAM spaces in order to save on repeated program/erase cycles. This chapter describes the Level 2 F021 Flash module controller (L2FMC).

Topic **Page**

7.1 Overview 339
7.2 Default Flash Configuration 340
7.3 EEPROM Emulation Support 340
7.4 SECDED 341
7.5 Memory Map 345
7.6 Power On, Power Off Considerations 350

7.1 Overview

The F021 Flash is used to provide non-volatile memory for instruction execution or data storage. The Flash can be electrically programmed and erased many times to ease code development.

Refer to the following documents for support on how to initialize and use the on-chip Flash and its API:

- *F021 (Texas Instruments 65nm Flash) Flash API Reference Guide* (SPNU501)

7.1.1 Features

- Symmetric dual port (Port A and Port B) for higher performance and concurrent access to different banks from one or more bus masters.
- Read, program and erase with a single 3.3 V supply voltage
- Supports error detection and correction
  - Single Error Correction and Double Error Detection (SECDED)
  - Error Correction Code (ECC) is evaluated in the CPU.
  - Address bits included in ECC calculation
- Provides different read modes to optimize performance and verify the integrity of Flash contents
- Provides software controllable power mode control logic
- Integrated program/erase state machine
  - Simplifies software algorithms
  - Supports simultaneous read access on up to two banks while performing a write or erase operation on any one of the remaining banks
  - Suspend command allows read access to a sector being programmed/erased
  - Fast erase and program times (for details, see the device-specific data sheet
- Allows remapping of Flash to RAM spaces through "Parameter Overlay Module" (POM)

For the actual size of the Flash memory for the device, see the device-specific data sheet.

7.1.2 Definition of Terms

Terms used in this document have the following meaning:

- bw - Normal data space bank data width of a Flash bank. The bw is 256 bits (288 bits including the error correction bits).
- bwe - EEPROM emulation bank is 64-bit wide (72 bits including the error correction bits).
- Bus Master - Any of CPU, DMA or other modules which can request data access.
- Charge pump: Voltage generators and associated control (logic, oscillator, and bandgap, for example).
- CSM: Program/erase command state machine
- Flash bank: A group of Flash sectors that share input/output buffers, data paths, sense amplifiers, and control logic.
- FEE - Flash EEPROM Emulation. Features on the L2FMC to support using a Flash type memory in place of an EEPROM Flash memory. EEPROM is erasable by the word while this Flash memory is only erasable by the sector. The FEE bank is accessible through the same bus as the main bank (in a special address range) and always resides in bank 7.
- Flash module: Flash banks, charge pump, and Flash wrapper.
- Flash wrapper: Power and mode control logic, data path, wait logic, and write/erase state machines.
- L2FMC - Level 2 Flash Module Controller.
- Command - A sequence of coded instructions to Flash module to execute a certain task.
- FSM (Flash State Machine) - State machine that parses and decodes FSM commands. It executes embedded algorithms and generates control signals to both Flash bank and charge pump during the actual program/erase operation.

Copyright © 2018, Texas Instruments Incorporated

- OTP (one-time programmable): A program-only-once Flash sector (cannot be erased)
- Sector: A contiguous region of Flash memory that must be erased simultaneously.
- Wide_Word - the width of the data output from the Flash bank. This is 288-bits wide for main Flash banks and 72-bits wide for the FEE bank.
- Prefetch Mode - Provides higher performance by fetching the subsequent cache line ahead of the actual request.
- Read Margin 1 mode: More stringent read mode designed for early detection of marginally erased bits.
- Read Margin 0 mode: More stringent read mode designed for early detection of marginally programmed bits.
- Implicit read - At startup the L2FMC performs multiple automatic reads from OTP to read device settings.
- Bus Error - L2FMC will generate a bus error to the bus master on certain accesses for example, writes to Flash on Port A/Port B or access to addresses beyond the available Flash space.
- POM - Parameter Overlay Module provides a method to remap the Flash when there is a need to have different values in the Flash contents without actually erasing and reprogramming the Flash.

7.1.3 F021 Flash Tools

Texas Instruments provides the following tools for F021 Flash:

- nowECC Generation Tool - to generate the Flash ECC from the Flash data.
- UNIFLASH Programming Tool - to erase/program/verify the device Flash content through JTAG.
- Code Composer Studio - the development environment with integrated Flash programming capabilities.
- F021 Flash API Library - a set of software peripheral functions to program/erase the Flash module. Refer to *F021 Flash API Reference Guide* (SPNU501) for more information.

7.2 Default Flash Configuration

At power up, the Flash module state exhibits the following properties:

- Wait states are set to 1 data wait state. An implicit address wait states are set to 1 and cannot be changed.
- Prefetch mode is enabled
- The Flash content is protected from modification
- Power modes are set to *Active* (no power savings)
- The boot code must initialize the wait states and the desired prefetch mode by initializing the FRDCNTL register to achieve the optimum system performance. This needs to be done before switching to the final device operating frequency.

7.3 EEPROM Emulation Support

Several features of the L2FMC support EEPROM emulation. They are listed here.

- In order to allow zeroing out used portions of Flash when the table has to be moved to a new block, L2FMC allows replacing the all-zero ECC with the correct ECC value of an all-zero 64b data. This is enabled by setting the EE_FEDACCTRL1.EZCV bit at address offset 8h.
- Similarly, in order to be able to read the Flash after successfully erasing it, L2FMC will compute the correct ECC for all-ones 64b data. This is enabled by setting the EE_FEDACCTRL1.EOCV bit at address offset 8h.
- Normally, for ECC to correctly work all the 64b of data must be programmed into the Flash. However, it is not uncommon to program partial words in the EEPROM Emulation bank. In order to allow this, L2FMC provides the FEDACSDIS and FEDACSDIS2 registers that identifies up to 4 chosen sectors where partial words may be programmed. In such a case, L2FMC computes ECC on the fly for these sectors thus avoiding any errors.

Copyright © 2018, Texas Instruments Incorporated

7.4 SECDED

The Flash memory can be protected by Single Error Correction Double Error Detection (SECDED). This protection is enabled by the SECDED circuit inside of the bus master.

7.4.1 SECDED Initialization

Flash error detection and correction is enabled at reset.

The ECC values for all of the Flash memory space (Flash banks 0 through 6) must be programmed into the Flash before the program/data can be read. This can be done by generating the correct values of the ECC with an external tool such as nowECC or may be generated by the programming tool. The Cortex R5F CPU may generate speculative fetches to any location within the Flash memory space. A speculative fetch to a location with invalid ECC, which is subsequently not used, will not create an abort, but will set the ESM flags for a correctable or uncorrectable error. An uncorrectable error will unconditionally cause the nERROR pin to toggle low. Therefore care must be taken to generate the correct ECC for the entire Flash space including the holes between sections and any unused or blank Flash areas.

The Cortex R5F CPU does not generate speculative fetches into the address space of bank 7, the EEPROM Emulation Flash. Therefore, it is only necessary to initialize the ECC values of the locations that will be intentionally read by the CPU or other bus masters.

7.4.2 ECC Encoding

Twenty-nine address lines are also included in the ECC calculation. A failure of a single address line inside of the bank will result in an uncorrectable error at the bus master. The ECC encoding is shown in Table 7-1.

7.4.3 Syndrome Table: Decode to Bit in Error

The syndrome is an 8-bit value that decodes to the bit in error. The bit in error can be a bit among the 64 data bits or a bit among the 8 ECC check bits. A syndrome value of 0000 0000 indicates there is no error. Any other syndrome combinations not shown in the table are uncorrectable multi-bit error. Errors of three of more bits may escape detection. The syndrome decoding is shown in Table 7-2.

7.5 Memory Map

The Flash module contains the program memory, which is mapped starting at location 0, and one Customer OTP sector and one TI OTP sector per bank. The Customer OTP sectors may be programmed by the customer, but cannot be erased. They are typically blank in new parts. The TI OTP sectors are used to contain manufacturing information. They may be read by the customer but can not be programmed or erased. The TI OTP sectors contain settings used by the Flash API to setup the Flash state machine for erase and program operations.

All of these OTP regions are memory-mapped to facilitate ease of access by the CPU. They are memory-mapped to an offset starting at F000 0000h in the CPUs memory map.

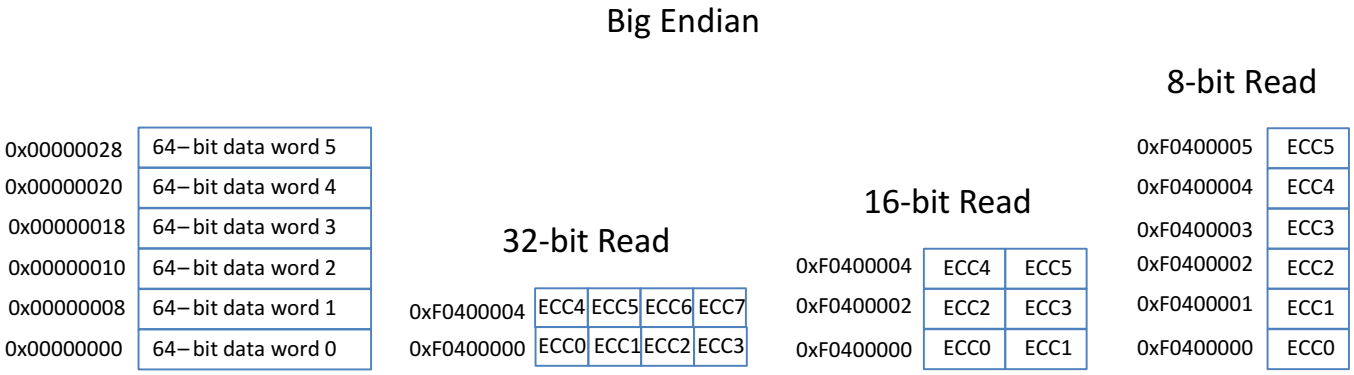
The RWAIT value is used to define the number of wait states for the program memory Flash. The EWAIT value is used to define the number of wait states for the data Flash in bank 7. Bank 7 starting at offset F020 0000h is dedicated for data storage such as EEPROM Emulation.

7.5.1 Location of Flash ECC Bits

The ECC bits are packed in their memory space as shown in Figure 7-1 and Figure 7-2.

NOTE: Unlike previous versions of this module, all the ECC bytes corresponding to the address and size of access are returned. For example, if a Load Multiple (LDM) was used to fetch 32 bytes of ECC, all of the actual bytes corresponding to the range of the access are returned. There is no replication of the bytes returned.

Figure 7-1. ECC Organization for Bank 0-1 (288-Bits Wide)



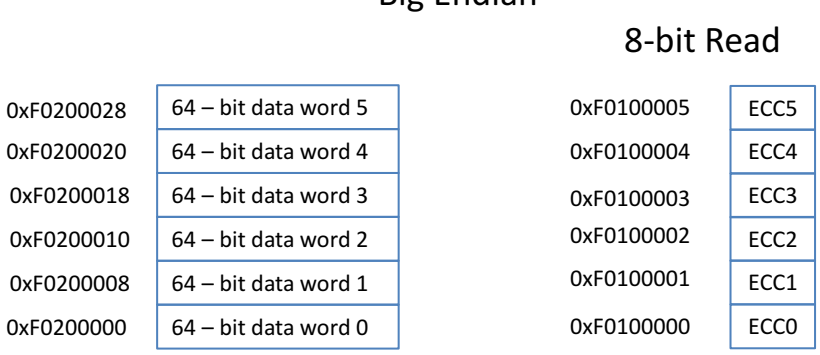


Figure 7-2. ECC Organization for Bank 7 (72-Bits Wide)

7.5.2 OTP Memory

7.5.2.1 Flash Bank and Sector Sizes

Flash Bank/Sectoring information can be determined from the device-specific datasheet or can be computed by reading locations in the TI OTP and L2FMC registers.

The number of banks, which banks are available, and the number of sectors for bank 0 can be read from TI OTP location F008 0158h as shown in Figure 7-3 and described in Table 7-4.

Figure 7-3. TI OTP Bank 0 Sector Information

31							24	23							16
Reserved								BX_NUM_Sectors							
R								R							
15							8	7							0
B7	B6	B5	B4	B3	B2	B1	B0	NUM_Banks

LEGEND: R = Read only

Table 7-4. TI OTP Bank 0 Sector Information Field Descriptions

Bit	Field	Value	Description
31-24	Reserved	0	Reserved. All bits will be read as 0.
23-16	BX_NUM_Sectors	1-32	Number of sectors in this bank.
15	B7	1	1 = Bank 7 is present
14	B6	0	0 = Bank 6 is not present
13	B5	0	0 = Bank 5 is not present
12	B4	0	0 = Bank 4 is not present
11	B3	0	0 = Bank 3 is not present
10	B2	0	0 = Bank 2 is not present
9	B1	1	1 = Bank 1 is present
8	B0	1	1 = Bank 0 is present
7-0	NUM_Banks	3	Number of banks on this part.

The bank sector information is repeated once for each bank in the device. The number of sectors is unique for each bank. The number of banks and which banks are implemented is repeated in each location. Use the TI OTP information for bank 0 to determine which banks are in the device, and then read the number of sectors for each bank using the TI OTP locations shown in Table 7-5.

Table 7-5. TI OTP Sector Information Address

Bank	TI OTP Address
0	F008 0158h
1	F008 2158h
2	F008 4158h
3	F008 6158h
4	F008 8158h
5	F008 A158h
6	F008 C158h

7.5.2.2 Package and Memory Size

Package and memory size information can be determined from the device-specific datasheet, or can be computed by reading locations in the TI OTP Bank 0 registers.

The package and memory size can be read from TI OTP location F008 015Ch as shown in Figure 7-4 and described in Table 7-6.

Figure 7-4. TI OTP Bank 0 Package and Memory Size Information

LEGEND: R = Read only

7.5.2.4 Part Number Symbolization

Device part number symbolization information can be determined from the device-specific data manual or can be computed by reading locations in the TI OTP bank 0 registers.

For example, the device part number symbolization "TMS570LC4357AZWTQQ1" can be read from TI OTP bank 0 location F008 01E0h through F008 01FFh as shown in Figure 7-6. The part number is stored as a null terminated ASCII string.

7.5.2.5 Temperature Sensor

There are three temperature sensors that can be used to read the internal junction temperature on this device. The temperature sensors are connected to the ADC converter. See Section 6.5.13 for information on how to select the temperature sensors. During device testing, the value read from the ADC along with the junction temperature of the silicon was recorded in the OTP at three different temperatures. These values can be read from TI OTP starting at location F008 0310h as shown in Figure 7-7 and described in Table 7-8. The values recorded were measured with ADREFHI equal to 3.3V.

F008 03xEh	16 bits	0xFFFF	Reserved

7.5.2.6 Deliberate ECC Errors for FMC ECC Checking

Deliberate single-bit and double-bit errors have been placed in the OTP for checking the L2FMC ECC functionality. Any portion of the 64 bits in TI OTP bank 0 location F008 03F0h through F008 03F7h as shown in Figure 7-10 will generate a single-bit error. Any portion of the 64 bits in TI OTP bank 0 location F008 03F8h through F008 03FFh as shown in Figure 7-10 will generate a double-bit error.

Figure 7-10. TI OTP Bank 0 Deliberate ECC Error Information

0x00	0x04	0x08	0x0C
0x12345678	0x9ABCDEF1	0x12345678	0x9ABCDEF3
R	R	R	R

LEGEND: R = Read only, * ECC is calculated for the value 0x123456789ABCDEF0

7.6 Power On, Power Off Considerations

7.6.1 Error Checking at Power On

As the device is coming out of the device reset sequence, the Flash wrapper reads a configuration word from the TI OTP section of bank 0. These are known as Implicit Reads. This is also readable from a bus master at address F008 0140h. During these reads ECC is enabled. Single-bit errors are corrected and uncorrectable errors will generate an error event. Accordingly, the IMPLICIT_COR_ERR or the IMPLICIT_UNC_ERR bits in the FEDAC_GBLSTATUS register (offset = 1Ch) will get set. Refer to the data manual to find the ESM group and channel number on which it is triggered.

7.6.2 Flash Integrity at Power Off

If power is lost during a programming or erase operation, a power-on reset must be asserted before the core supply voltage drops below specification. The $\overline{\text{PORRST}}$ pin has a glitch filter that means that the $\overline{\text{PORRST}}$ pin must be asserted low $t_{f(nPORRST)}$ (2 µs) before the core supply drops below Vcc_{MIN} (1.14V). If this requirement is met, then the bits being programmed when $\overline{\text{PORRST}}$ goes low are indeterminate; however, the other bits in the Flash are not disturbed. Likewise, if this requirement is met, and $\overline{\text{PORRST}}$ is asserted while erasing, the sector or sectors being erased will have indeterminate bits; however, the other sectors in the same bank and the other banks will not be disturbed.

7.7 Emulation and SIL3 Diagnostic Modes

7.7.1 System Emulation

During emulation when the SUSPEND signal is high, address tag and command parity error events are not generated.

7.7.2 Diagnostic Mode

The Flash wrapper can be put in diagnostic mode to verify various logic. There are multiple diagnostic modes supported by the wrapper. A specific diagnostic mode is selected via the DIAGMODE control bits in the diagnostic control register (FDIAGCTRL), as listed in Table 7-9.

The diagnostic mode is only enabled by a 4-bit key stored in the DIAG_EN_KEY bits in FDIAGCTRL register. Only DIAG_EN_KEY = 5h enables any diagnostic mode and all diagnostic modes use the DIAG_TRIG bit in FDIAGCTRL register to initiate the action.

For all modes it is best to follow this sequence:

1. Write 5h to the DIAG_EN_KEY bits and set the desired DIAGMODE control bits.
2. Set any data registers needed for this mode.
3. Write a 1 to the DIAG_TRIG bit to initiate the action and allow an error to happen.
4. Write a Ah to the DIAG_EN_KEY bits to disable the diagnostic modes.

Table 7-9. DIAGMODE Encoding

Mode	DIAGMODE Bits			Description
0	0	0	0	Diagnostic mode is disabled. Same as DIAG_EN_KEY not equal to 5h.
5	1	0	1	Address Tag Register test mode
7	1	1	1	ECC Data Correction Diagnostic test mode
Others	Other Combinations			Reserved

Copyright © 2018, Texas Instruments Incorporated

7.7.2.1 Address Tag Register Test Mode: DIAGMODE = 5

There are six sets of address tag registers, two for Port A and four for Port B. Each set consists of a primary and a duplicate address tag registers. Normally, these registers store the recently issued CPU addresses during prefetch mode. To detect errors in these registers, the primary and duplicate address tag registers are continuously compared to each other if the buffer is valid. If they are different, then an address tag register error event is generated.

These registers are memory-mapped. All primary address tag registers are memory-mapped to one address and, likewise, all duplicate tag registers are mapped to another single address. During diagnostic mode, each individual set can be selected by the DIAG_BUF_SEL (Diagnostic Buffer Select) bit in the FDIAGCTRL register. User-supplied values can be written into the selected set during a diagnostic mode. This diagnostic mode uses the FRAW_ADDR register to supply the alternate address. When the DIAG_TRIG bit is set, the FRAW_ADDR register value is compared with the primary and the duplicate address tag registers. If the results of the comparison are different, then the ADD_TAG_ERR (Address Tag Error) flag in the FEDAC_PxSTATUS register will be set. Also, refer to the device data manual for the specific error channel that will be asserted in this situation.

The sequence to do this test would be:

1. Branch to a non-Flash region for executing this sequence. Ensure no requests from any bus master are arriving at the port (A or B) that is being diagnosed.
2. Set DIAGMODE to 5h and DIAG_EN_KEY to 5h in the FDIAGCTRL register.
3. Select the appropriate buffer to be diagnosed using the DIAG_BUF_SEL bits in the FDIAGCTRL register using the table in Section 7.10.23.
4. Set the FRAW_ADDR register to a certain arbitrary value 'A'. The lowest 5 bits should be cleared to 0.
5. Set the FPRIM_ADD_TAG register and the FDUP_ADD_TAG register in such a way that one of them equals 'A' and the other one does not. The lowest 5 bits in both these writes should be cleared to 0.
6. Set the DIAG_TRIG bit in the FDIAGCTRL register.
7. Now check the appropriate ADD_TAG_ERR flag in the FEDAC_PxSTATUS register based on the port being diagnosed. Ensure that it is 1, implying successful operation of the compare logic.
8. Write 1 to the ADD_TAG_ERR bit to clear it.
9. Repeat for the different buffers.
10. At the end of the test, clear DIAGMODE bit to 0 and set DIAG_EN_KEY bits to Ah in the FDIAGCTRL register to completely disable the test.

All address tags and buffer valid bits will be cleared to 0 when leaving diag_mode 5.

NOTE: You should pre-load the registers with the test values with DIAG_TRIG = 0. After all test values are written, the DIAG_TRIG should then be set high to validate the diagnostic result.

Copyright © 2018, Texas Instruments Incorporated

7.7.2.2 ECC Data Correction Diagnostic Test Mode: DIAGMODE = 7

Testing the error correction and ECC logic in the CPU involves corrupting the ECC value returned to the CPU. By inverting one or more bits of the ECC, the CPU will detect errors in a selected data or ECC bit, or in any possible value returned by the ECC.

To set an error for a particular bit use the syndrome, see Section 7.4.3. For example, if you want to corrupt data bit 62 then put the value 70h into the test register.

The method uses the FEMU_ECC and the FEMU_DxSW registers to alter the ECC and data, respectively, for one Flash access port read. The values in the FEMU_ECC and FEMU_DxSW registers will be XORed with the current ECC and data, respectively, to give a bad ECC or data value back to the bus master. This will only occur for one read when the DIAGMODE is 7h, the DIAG_EN_KEY is 5h, and the DIAG_TRIG is written with value of 1 in the FDIAGCTRL register.

The sequence to do this test is:

1. Branch to a non-Flash region to execute this sequence.
2. Set DIAGMODE to 7h and DIAG_EN_KEY to 5h in the FDIAGCTRL register.
3. Set desired values to XOR in the FEMU_ECC and FEMU_DxSW registers.
4. Set DIAG_TRIG to 1 in the FDIAGCTRL register.
5. Select the appropriate port in which the flip is desired using the DIAG_BUF_SEL bits in the FDIAGCTRL register. Only legal values are 0 for port A and 4h for port B.
6. Do a port A or B read to the desired address. The L2FMC will XOR the data and ECC with FEMU_DxSW and FEMU_ECC, respectively, for this read before delivering it to the CPU. No further reads are affected by this diagnostic.
7. The error routine of the bus master (for example, CPU) shall cause the address and erroneous bit to be known. This should match with the bit flipped in step 3.
8. Repeat as necessary to test out various bits of data and ECC.
9. Clear DIAGMODE to 0 and set DIAG_EN_KEY to Ah in the FDIAGCTRL register to completely disable this test.

NOTE: Make sure the address to be used for diagnostic is not already cached; otherwise, the read will read from the cache memory instead of the Flash.

7.7.3 Diagnostic Mode Summary

Table 7-10 gives a summary of the input registers needed for each mode, the possible registers that can change, and the possible error bits in FEDACSTATUS that may set.

Table 7-10. Diagnostic Mode Summary

DIAG MODE	Name	Inputs	Possible Outputs	Possible Error Bits Set	Notes
5	Address Tag Register test mode	FPRIM_ADD_TAG FDUP_ADD_TAG FRAW_ADDR		ADD_TAG_ERR in FEDAC_PxSTATUS register	This will cause ESM error. Please refer to the data manual to find group and channel number.
7	ECC Data Correction Diagnostic test mode	FEMU_ECC FEMU_DxSW	Bus master will indicate data ECC single-bit or multi-bit error.	None	This will cause ESM error. Please refer to the data manual to find group and channel number.

7.7.4 SECDED Software Diagnostic

The SECDED block is used to perform error detection and correction on the implicit reads made after reset by L2FMC. To simplify the diagnostic for this logic, a software mechanism is used. To check that the SECDED module correctly performed its operation, the following steps must be used:

1. CPU reads the 64-bit memory location of the implicit read. For example, implicit read location is at 0xF008_0140.
2. Next, CPU reads the memory mapped registers RCR_VALUEx registers accessible at address offsets D0h and D4h.
3. The two 64-bit values read in steps 1 and 2 are compared for being equal.
   a. If the two values are equal, then the location in memory after correction by the CPU SECDED is the same value as location in memory after correction by L2FMC SECDED. Assuming the CPU SECDED can be independently verified, the L2FMC SECDED must be functioning correctly.
   b. If the two values are not equal, then L2FMC SECDED is not functioning correctly.

7.7.5 Read Margin

When the bits are programmed or erased, they are checked against a program_verify or erase_verify reference level that is far away from the normal read reference point. Over time, bit levels may drift toward the normal read point and if it is too much then a bit will read the wrong value. To counteract this, the bits can be read using different read_margin reference points to give an early detection of the problem. The bits can then be either re-programmed (most common) or the sector can be erased and reprogrammed.

7.8 Parameter Overlay Module (POM)

In many applications it is important to be able to change certain parameters in the program without having to re-flash the device and immediately test these changes either in a hardware-in-the-loop simulation or in a real environment. The Parameter Overlay Module (POM) helps to achieve this goal. The POM provides a mechanism to redirect accesses to non-volatile memory into a volatile memory that can be internal to the device or external. The data requested by the master will be fetched from the overlay memory instead of the main non-volatile memory. The overlay memory can be accessed by other masters in the system to provide an easy update path of the stored data. Other masters can be, for example, the main CPU, DMA, DMM, or DAP AHB-AP.

7.8.1 Example Procedure to Configure the POM

Suppose the intent is to remap 128KB of Flash at address 10_0000h to 8000_0000h. Note that both program region and overlay region have to be aligned to the size of the region. Sequence to perform this configuration would be as follows:

1. Ensure that there are no active accesses to this space while the following configuration is ongoing.
2. Write to the POMGLBCTRL.OTADDR (offset 0h) a value of 200h. These are the upper 10bits of the overlay region base address.
3. Write to the POMPROGSTART0.STARTADDRESS (offset 200h) a value of 0x10_0000h.
4. Write to the POMOVLSTART0.STARTADDRESS (offset 204h) a value of 00_0000h. These are the bits 21-17 of the overlay region address. Since the region size is 128KB the lower bits do not matter.
5. Write to the POMREGSIZE0.SIZE (offset 208h) a value of Ch.
6. Finally write to the POMGLBCTRL.ON_OFF to Ah.
7. End of sequence.

7.9 Summary of L2FMC Errors

Table 7-11. Errors in L2FMC

Scenario	Does this error cause a Bus Error?	Does this error go to ESM?	Is a flag in L2FMC set?	Name of Flag
Access parity error/Internal parity errors	Yes	Yes	Yes	FEDAC_PxSTATUS. ADD_PAR_ERR
Port A/B Idle State parity error	No	Yes	Yes	FEDAC_PxSTATUS. MCMD_PAR_ERR
Address tag error	Yes	Yes	Yes	FEDAC_PxSTATUS. ADD_TAG_ERR
Access to Flash space beyond available size	Yes	No	No	-
Access to Flash while pump/bank are not active	Yes	No	No	-
Flash Access time-out	Yes	Yes	Yes	FEDAC_PxSTATUS. ACC_TOUT
Invalid access to L2FMC (for example, writes)	Yes	No	No	-
Single-bit Error during Implicit Reads	No	Yes	Yes	FEDAC_GBLSTATUS. IMPLICIT_COR_ERR
Uncorrectable Error during Implicit Reads	No	Yes	Yes	FEDAC_GBLSTATUS. IMPLICIT_UNC_ERR
Access to bank while program/erase operations are ongoing on the same bank	Yes	No	No	-
Access to register address offsets between 2C8h and 3FFh or 4B8h and 7FFh	Yes	No	No	-
Redirected access to POM received a bus error	Yes	No	No	-
Response of redirected access to POM has access parity error	Yes	No	Yes	POMFLG.PERR_Px
POM Idle State parity error	No	Yes	Yes	FEDAC_PxSTATUS. MCMD_PAR_ERR
Soft Errors in high integrity bits carrying Implicit read data	No	Yes	Yes	FEDAC_GBLSTATUS. RCR_ERR

7.10 Flash Control Registers

This section details the Flash module registers, summarized in Table 7-12. The Flash module control registers can only be read and/or written by the CPU while in privileged mode. Each register begins on a word boundary. All registers are 32-bit, 16-bit and 8-bit accessible. The start address of the Flash module is FFF8 7000h.

Table 7-12. Flash Control Registers

7.10.1 Flash Read Control Register (FRDCNTL)

FRDCNTL supports prefetch mode. This register controls Flash timings for the main Flash banks. For the equivalent register that controls Flash timings for the EEPROM Emulation Flash bank (bank 7), see Section 7.10.32.

Figure 7-11. Flash Read Control Register (FRDCNTL) (offset = 00h)

7.10.3 EEPROM Error Correction Control Register (EE_FEDACCTRL1)

When a EEPROM bank is erased or zeroed out, the contents will be all 1's or all 0's, respectively. In such a case, the ECC will be incorrect. EE_FEDACCTRL1 lets the L2FMC ignore an all 1's and all 0's condition, on reads from the EEPROM bank.

7.10.4 Flash Port A Error and Status Register (FEDAC_PASTATUS)

This register applies to accesses made to the main or EEPROM Flash banks through Port A.

All these error status bits can be cleared by writing a 1 to the bit; writing a 0 has no effect.

Figure 7-14. Flash Port A Error and Status Register (FEDAC_PASTATUS) (offset = 14h)

LEGEND: R = Read only; RCP = Read and Clear in Privilege Mode; -u = unchanged value on internal reset, cleared on power up; *-n* = value after reset

Table 7-16. Flash Port A Error and Status Register (FEDAC_PASTATUS) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
15	ACCTOUT		Severe internal switch timeout/parity error on Port A access.
		0	L2FMC internal switch has NOT encountered a severe error (access timeout or parity).
		1	L2FMC internal switch has encountered a severe error (access timeout or parity).
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
14	MCMD_PAR_ERR		Parity Error in idle state. This bit is set when a parity error occurs during idle state of Port A.
		0	No idle state parity error is detected.
		1	Parity error is detected in idle state.
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
13-12	Reserved	0	Reads return 0. Writes have no effect.
11	ADD_TAG_ERR		Port A Address Tag Register Error Flag. This bit is set if the primary address tag has a hit but the duplicate address tag does not match the primary address tag. This bit is functional only when Port A prefetch mode is enabled (PFUENA = 1).
		0	Address Tag Register Error not detected on Port A.
		1	Address Tag Register Error detected on Port A.
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
10	ADD_PAR_ERR		Address Parity Error Flag.
		0	No parity error was detected on the incoming access to the L2FMC Port A.
		1	A parity error was detected on the incoming access to the L2FMC Port A. The address of the erroneous access is not stored in L2FMC.
			This error is routed to the ESM. Refer to the device data manual to find the specific group and channel on which it is routed.
9-0	Reserved	0	Reads return 0. Writes have no effect.

7.10.5 Flash Port B Error and Status Register (FEDAC_PBSTATUS)

This register applies to accesses made to the main or EEPROM Flash banks through Port B.

All these error status bits can be cleared by writing a 1 to the bit; writing a 0 has no effect.

Figure 7-15. Flash Port B Error and Status Register (FEDAC_PBSTATUS) (offset = 18h)

LEGEND: R = Read only; RCP = Read and Clear in Privilege Mode; -u = unchanged value on internal reset, cleared on power up; *-n* = value after reset

Table 7-17. Flash Port B Error and Status Register (FEDAC_PBSTATUS) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
15	ACCTOUT		Severe error - internal switch timeout.
		0	L2FMC internal switch has NOT encountered a severe error (access timeout).
		1	L2FMC internal switch has encountered a severe error (access timeout).
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
14	MCMD_PAR_ERR		Parity Error in idle state. This bit is set when a parity error occurs during idle state of Port B.
		0	No idle state parity error is detected.
		1	Parity error is detected in idle state.
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
13-12	Reserved	0	Reads return 0. Writes have no effect.
11	ADD_TAG_ERR		Port B Address Tag Register Error Flag. This bit is set if the primary address tag has a hit but the duplicate address tag does not match the primary address tag. This bit is functional only when Port B prefetch mode is enabled (PFUENB = 1).
		0	Address Tag Register Error not detected on Port B.
		1	Address Tag Register Error detected on Port B.
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
10	ADD_PAR_ERR		Address Parity Error Flag.
		0	No parity error was detected on the incoming access to the L2FMC Port B.
		1	A parity error was detected on the incoming access to the L2FMC Port B. The address of the erroneous access is not stored in L2FMC.
			This error is routed to the ESM. Refer to the device data manual to find the specific group and channel on which it is routed.
9-0	Reserved	0	Reads return 0. Writes have no effect.

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24	FSM_DONE		Flash State Machine Done This bit is set to 1 when the Flash state machine completes a program or erase operation. This bit will generate an interrupt on VIM channel 61 if the FSM_EVT_EN bit of the FSM_ST_MACHINE register is set. This bit must be cleared by writing a 1 to it in the interrupt routine to clear the interrupt request.
23-16	Reserved	0	Reads return 0. Writes have no effect.
15	RCR_ERR		Soft error in high integrity bits carrying implicit read data.
		0	No error detected in high-integrity bits.
		1	Error detected in high-integrity bits.
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
14	IMPLICIT_COR_ERR		Correctable error occurred during implicit reads.
		0	No single-bit error is detected during implicit read.
		1	Single-bit error is detected during implicit read.
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
13	IMPLICIT_UNC_ERR		Uncorrectable error occurred during implicit reads.
		0	No double-bit error is detected during implicit read.
		1	Double-bit error is detected during implicit read.
			This error is routed to the ESM. Refer to the device data manual to find the group and channel on which it is routed.
12-0	Reserved	0	Reads return 0. Writes have no effect.

7.10.7 Flash Error Detection and Correction Sector Disable Register (FEDACSDIS)

This register is used to disable the SECDED function for one or two sectors from the EEPROM Emulation Flash (bank 7). An additional two sectors can have SECDED disabled by the use of the FEDACSDIS2 register (see Section 7.10.28).

Figure 7-17. Flash Error Detection and Correction Sector Disable Register (FEDACSDIS) (offset = 24h)

7.10.8 Primary Address Tag Register (FPRIM_ADD_TAG)

This register is used to test the prefetch address tag registers. (see Section 7.7.2.1)

Figure 7-18. Primary Address Tag Register (FPRIM_ADD_TAG) (offset = 28h)

LEGEND: R/W = Read/Write; R = Read only; WP = Write in Privilege Mode; -*n* = value after reset

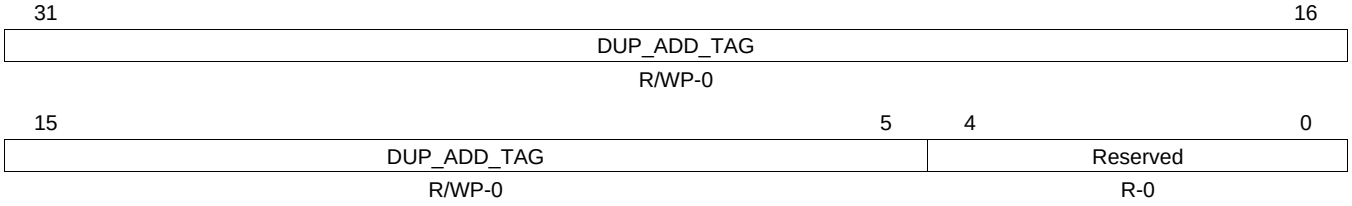

Table 7-20. Primary Address Tag Register (FPRIM_ADD)_TAG Field Descriptions

Bit	Field	Value	Description
31-5	PRIM_ADD_TAG	0-7FF FFFFh	Primary Address Tag Register The primary address tag register selected by the DIAG_BUF_SEL bits in the FDIAGCTRL register is memory-mapped here. This register can only be written in privileged mode when diagnostic mode is enabled with DIAG_EN_KEY = 5h and DIAGMODE = 5h in the FDIAGCTRL register. This register is not updated with new Flash data if DIAG_EN_KEY is not equal to 5h or DIAGMODE is 0 or 7h. Valid reads can occur in any mode. The register clears when an address tag error is found and when leaving DIAG_MODE 5.
4-0	Reserved	0	Reads return 0. Writes have no effect.

7.10.9 Duplicate Address Tag Register (FDUP_ADD_TAG)

This register is used to test the prefetch address tag registers. (see Section 7.7.2.1)

Figure 7-19. Duplicate Address Tag Register (FDUP_ADD_TAG) (offset = 2Ch)

LEGEND: R/W = Read/Write; R = Read only; WP = Write in Privilege Mode; -*n* = value after reset

Table 7-21. Duplicate Address Tag Register (FDUP_ADD)_TAG Field Descriptions

Bit	Field	Value	Description
31-5	DUP_ADD_TAG	0-7FF FFFFh	Duplicate Address Tag Register The duplicate address tag register selected by the DIAG_BUF_SEL bits in the FDIAGCTRL register is memory-mapped here. This register can only be written in privileged mode when diagnostic mode is enabled with DIAG_EN_KEY = 5h and DIAGMODE = 5h in the FDIAGCTRL register. This register is not updated with new Flash data if DIAG_EN_KEY is not equal to 5h or DIAGMODE is 0 or 7h. Valid reads can occur in any mode. The register clears when an address tag error is found and when leaving DIAG_MODE 5.
3-0	Reserved	0	Reads return 0. Writes have no effect.

Table 7-22. Flash Bank Protection Register (FBPROT) Field Descriptions

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	PROTL1DIS		Level 1 Protection Disable bit Setting this bit disables protection from writing to the OTPPROTDIS bits in the FBAC register as well as the BSE bits for all banks in the FBSE register. Clearing this bit enables protection and disables write access to the OTPPROTDIS bits and FBSE register.
		0	Level 1 protection is enabled.
		1	Level 1 protection is disabled.

7.10.11 Flash Bank Sector Enable Register (FBSE)

FBSE provides one enable bit per sector for up to 16 sectors per bank. Each bank in the Flash module has one FBSE register. The bank is selected via the BANK bits in the FMAC register. As only one bank at a time can be selected by FMAC, only the register for the bank selected appears at this address.

R-1	R-0		R-1	R-0		R-1	

LEGEND: R = Read only; -*n* = value after reset

Table 7-27. Flash Bank/Pump Ready Register (FBPRDY) Register Description

Bit	Field	Value	Description
31-24	Reserved	0	Reads return 0. Writes have no effect.
23	BANKBUSY[7]		Bank 7 Busy Status
		0	Bank is not busy with any FSM or CPU operation.
		1	Bank is busy with an FSM or CPU operation.
22-18	Reserved	1	Reads return 1. Writes have no effect.
17-16	BANKBUSY[1:0]		Bank 0 (bit 16) and Bank 1 (bit 17) Busy Status
		0	Bank is not busy with any FSM or CPU operation.
		1	Bank is busy with an FSM or CPU operation.
15	PUMPRDY		Pump Ready is a read-only bit which allows software to determine if the pump is ready for Flash access before attempting the actual access. When set, it means that the charge pump is in active power state. If an access is made to a bank which is not ready then wait states are asserted until it becomes ready
		0	Pump is not ready.
		1	Pump is ready.
14-8	Reserved	0	Reads return 0. Writes have no effect.
7	BANKRDY[7]		Bank 7 Ready Status
		0	Bank is not ready for Flash access.
		1	Bank is ready for Flash access.
6-2	Reserved	0	Reads return 0. Writes have no effect.
1-0	BANKRDY[1:0]		Bank 0 (bit 0) and Bank 1 (bit 1) Ready Status
		0	Bank is not ready for Flash access.
		1	Bank is ready for Flash access.

Reserved		PSLEEP	
R-0		R/WP-C8h	

15	1	0
Reserved		PUMPPWR
R-0		R/WP-1

LEGEND: R/W = Read/Write; R = Read only; WP = Write in Privilege Mode; -*n* = value after reset

Table 7-28. Flash Pump Access Control Register 1 (FPAC1) Field Descriptions

Bit	Field	Value	Description
31-12	Reserved	0	Reads return 0. Writes have no effect.
26-16	PSLEEP	0-7FFh	Pump Sleep. These bits contain the starting count value for the charge pump sleep down counter. While the charge pump is in sleep mode, the power mode management logic holds the charge pump sleep counter at this value. When the charge pump exits sleep power mode, the down counter delays from 0 to PSLEEP pump sleep down clock cycles before putting the charge pump into active power mode. **Note:** Pump sleep down counter clock is a divide by 2 input of HCLK. That is, there are 2 × HCLK cycles for every PSLEEP counter cycle.
15-1	Reserved	0	Reads return 0. Writes have no effect.
0	PUMPPWR		Flash Charge Pump Fallback Power Mode
		0	Sleep (all pump circuits are disabled)
		1	Active (all pump circuits are active)

LEGEND: R/W = Read/Write; R = Read only; WP = Write in Privilege Mode; -*n* = value after reset

Table 7-29. Flash Module Access Control Register (FMAC) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
2-0	BANK	0-7h	Bank Enable. These bits select which bank is enabled for operations such as local register access, OTP sector access, and program/erase commands. These bits select only one bank at a time from up to eight banks depending on the specific device being used. For example, a 000 selects bank 0; 011 selects bank 3. **Note:** BANK can identify up to 8 Flash banks. If BANK is selected for an un-implemented bank, then the BANK will set itself to the number of an implemented bank. To determine if a bank is implemented, write the bank number to BANK and read back the value to see if what was written can be read back.

LEGEND: R = Read only; -*n* = value after reset

Table 7-30. Flash Module Status Register (FMSTAT) Field Descriptions

Bit	Field	Value	Description
31-18	Reserved	0	Reads return 0. Writes have no effect.
17	RVSUSP		Read Verify Suspend
		1	When set, this bit indicates that the Flash module has received and processed a suspend command during a read-verify operation. This bit remains set until the read-verify-resume command has been issued or the Clear_More command is run.
16	RVDER		Read verify command currently underway
		1	When set, this bit indicates that the Flash module is actively performing a read-verify operation. This bit is set when read-verify starts and is cleared when it is complete. It is also cleared when the read-verify is suspended and set when the read-verify resumes.
15	RVF		Read Verify Failure
		1	When set, indicates that a read verify mismatch is detected using the Read Verify command. This bit remains set until clear_status or clear_more FSM commands are run.
14	ILA		Illegal Address
		1	When set, indicates that an illegal address is detected. The following conditions can set the illegal address flag. 1. Writing to a hole (un-implemented logical address space) within a Flash bank. 2. Writing to an address location to an un-implemented Flash space. 3. Input address for write is decoded to select a different bank from the bank ID register. 4. The address range does not match the type of FSM command. For example, the erase_sector command must match the address regions. 5. TI-OTP address selected but CMD_EN in FSM_ST_MACHINE is not set.
13	DBT		Disturbance Test Fail
		1	This bit is set during a Program Sector command when the FSM first reads an address and it is not all 1s.
12	PGV		Program Verify
		1	When set, indicates that a word is not successfully programmed after the maximum allowed number of program pulses are given for program operation.
11	PCV		Precondition Verify.
		1	When set, indicates that a sector is not successfully preconditioned (pre-erased) after the maximum allowed number of program pulses are given for precondition operation for any applied command such as Erase Sector command. During Precondition verify command, this flag is set immediately if a Flash bit is found to be 1.

Copyright © 2018, Texas Instruments Incorporated

Table 7-30. Flash Module Status Register (FMSTAT) Field Descriptions (continued)

Bit	Field	Value	Description
10	EV		Erase Verify
		1	When set, indicates that a sector is not successfully erased after the maximum allowed number of erase pulses are given for erase operation. During Erase verify command, this flag is set immediately if a bit is found to be 0.
9	CV		Compact Verify
		1	When set, indicates that a sector contains one or more bits in depletion after an erase operation with CMPV_ALLOWED set. During compact verify command, this flag is set immediately if a bit is found to be 1.
8	BUSY		Busy
		1	When set, this bit indicates that a program, erase, or suspend operation is being processed.
7	ERS		Erase Active
		1	When set, this bit indicates that the Flash module is actively performing an erase operation. This bit is set when erasing starts and is cleared when erasing is complete. It is also cleared when the erase is suspended and set when the erase resumes.
6	PGM		Program Active
		1	When set, this bit indicates that the Flash module is currently performing a program operation. This bit is set when programming starts and is cleared when programming is complete. It is also cleared when programming is suspended and set when programming is resumes.
5	INVDAT		Invalid Data
		1	When set, this bit indicates that the user attempted to program a 1 where a 0 was already present. This bit is cleared by the Clear Status command.
4	CSTAT		Command Status
		1	Once the FSM starts any failure will set this bit. When set, this bit informs the host that the program, erase, or validate sector command failed and the command was stopped. This bit is cleared by the Clear Status command. For some errors, this will be the only indication of an FSM error because the cause does not fall within the other error bit types.
3	VOLTSTAT		Core Voltage Status
		1	When set, this bit indicates that the core voltage generator of the pump power supply dipped below the lower limit allowable during a program or erase operation. This bit is cleared by the Clear Status command.
2	ESUSP		Erase Suspended
		1	When set, this bit indicates that the Flash module has received and processed an erase suspend operation. This bit remains set until the erase resume command has been issued or until the Clear_More command is run.
1	PSUSP		Program Suspended
		1	When set, this bit indicates that the Flash module has received and processed a program suspend operation. This bit remains set until the program resume command has been issued or until the Clear_More command is run.
0	SLOCK		Sector Lock Status
		1	When set, this bit indicates that the operation was halted because the target sector was locked for erasing and programming either by the sector protect bit or by OTP write protection disable bits. (BSE bits in the FBSE register or OTPPROTDIS bits in the FBAC register). This bit is cleared by the Clear Status command. No SLOCK FSM error will occur if all sectors in a bank erase operation are set to 1. All the sectors will be checked but no SLOCK will be set if no operation occurs due to the SECT_ERASED bits being set to all 1s. A SLOCK error will occur if attempting to do a sector erase with either BSE is cleared or SECT_ERASED is set.

7.10.23 Diagnostic Control Register (FDIAGCTRL)

First set the DIAGMODE and the DIAG_EN_KEY bits before setting up the other registers to block the other registers from causing a false error. The final write should set the DIAG_TRIG bit to activate the test. Running out of RAM will prevent problems with the diagnostic test corrupting the Flash access in some of the modes.

Figure 7-33. Diagnostic Control Register (FDIAGCTRL) (offset = 6Ch)

LEGEND: R/W = Read/Write; R = Read only; WP = Write in Privilege mode; -*n* = value after reset

Table 7-35. Diagnostic Control Register (FDIAGCTRL) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24	DIAG_TRIG		Diagnostic Trigger Diagnostic trigger is the final qualifier for the diagnostic result. After setting all the other diagnostic register values, the DIAG_TRIG is set to 1. This activates the diagnostic logic for one access and then automatically clears the DIAG_TRIG value. The DIAG_EN_KEY and DIAGMODE bits must be set before setting DIAG_TRIG. This bit always reads as 0.
23-20	Reserved	0	Reads return 0. Writes have no effect.
19-16	DIAG_EN_KEY		Diagnostic Enable Key
		5h	Diagnostic mode is enabled.
		All other values	Diagnostic mode is disabled.
15-11	Reserved	0	Reads return 0. Writes have no effect.
10-8	DIAG_BUF_ SEL		Diagnostic Buffer Select
		0	During diagnostic mode 5 the DIAG_BUF_SEL selects the buffer to read or write when accessing the FPRIM_ADD_TAG and FDUP_ADD_TAG registers. The address tags consists of matching primary and duplicate address tag registers. All the primary address tag registers are memory mapped to a common address (see Section 7.10.8) and are selected by DIAG_BUF_SEL. The same occurs for the duplicate address (see Section 7.10.9). Port A has 2 buffers and Port B has 4 buffers. During diagnostic mode 7 the value selects the port on which to perform the diagnostic.
		0	Port A Buffer 0 (diag mode 5) / Port A selected to flip data/ECC (diag mode 7)
		1h	Port A Buffer 1 (diag mode 5) / Reserved in diag mode 7
		2h	Reserved
		3h	Reserved
		4h	Port B Buffer 0 (diag mode 5) / Port B selected to flip data/ECC (diag mode 7)
		5h	Port B Buffer 1 (diag mode 5) / Reserved (diag mode 7)
		6h	Port B Buffer 2 (diag mode 5) / Reserved (diag mode 7)
		7h	Port B Buffer 3 (diag mode 5) / Reserved (diag mode 7)
7-4	Reserved	0	Reads return 0. Writes have no effect.
2-0	DIAGMODE		Diagnostic Mode (Only values 0, 5, and 7 are valid. Other values are reserved).
		0	Diagnostic mode is disabled. This is the same as DIAG_EN_KEY is not equal to 5h.
		5h	Address Tag Register test mode (see Section 7.7.2.1).
		7h	ECC Data Correction Diagnostic test mode (see Section 7.7.2.2).

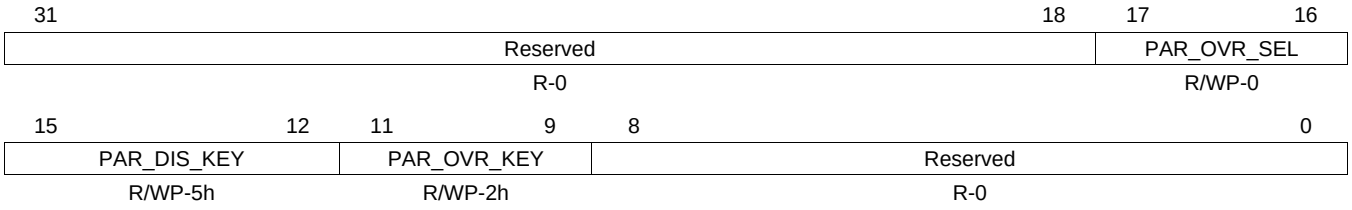
7.10.24 Raw Address Register (FRAW_ADDR)

Figure 7-34. Raw Address Register (FRAW_ADDR) (offset = 74h)

31	5	4	0
RAW_DATA[31:5]		Reserved	
R/WP-u		R-0	

LEGEND: R/W = Read/Write; R = Read only; WP = Write in Privilege mode; -u = Unchanged value on internal reset, cleared on power up; -*n* = value after reset

Table 7-36. Raw Address Register (FRAW_ADDR) Field Descriptions



Bit	Field	Description
31-5	RAW_DATA	Raw Address. This register is used during the address tag register test mode, DIAGMODE = 5, to replace the address bus bits 31:3. The lower 5 bits are not compared during the diagnostic.
4-0	Reserved	Reads return 0. Writes have no effect.

Copyright © 2018, Texas Instruments Incorporated

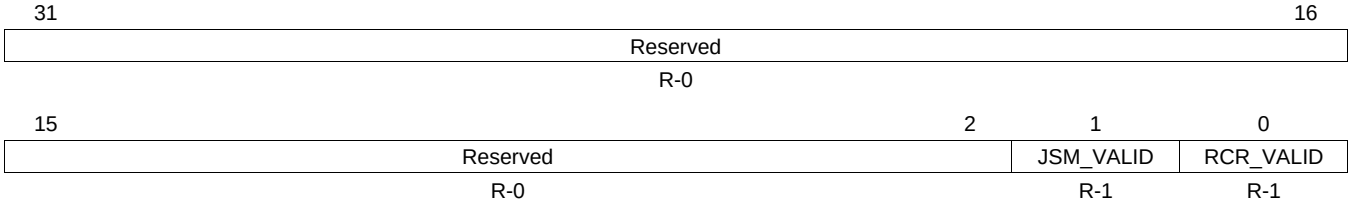
7.10.25 Parity Override Register (FPAR_OVR)

This register allows overriding the parity that is internally computed by the L2FMC for checking the parity circuit.

Figure 7-35. Parity Override Register (FPAR_OVR) (offset = 7Ch)

LEGEND: R/W = Read/Write; R = Read only; WP = Write in Privilege Mode; -*n* = value after reset

Table 7-37. Parity Override Register (FPAR_OVR) Field Descriptions



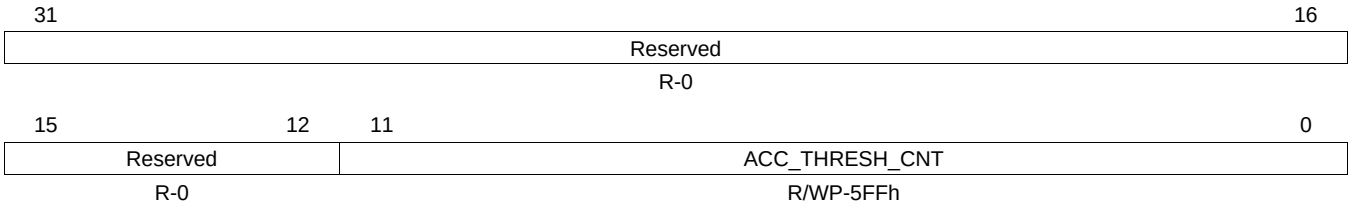
Bit	Field	Value	Description
31-18	Reserved	0	Reserved
17-16	PAR_OVR_SEL		Select which parity checker to invert the polarity of the parity.
		0	No effect.
		1h	Idle state parity checker received inverted parity polarity.
		2h	Command parity checker receives inverted parity polarity.
		3h	Internal address parity checker receives inverted parity polarity
15-12	PAR_DIS_KEY		Disable access Parity. ECC on Data is NOT affected by this setting and behaves the same way.
		Ah	The access parity error is disabled and no checking is done and no events are generated.
		All other values	Any other value enables the parity checking on the access.
11-9	PAR_OVR_KEY		Parity Override
		5h	The selected parity checker selected through PAR_OVR_SEL will receive inverted SYS_ODD_PARITY.
		All other values	Any other value causes the module to use the global system parity bit in the system register DEVCR1.
8-0	Reserved	0	Reads return 0. Writes have no effect.

Copyright © 2018, Texas Instruments Incorporated

7.10.26 Reset Configuration Valid Register (RCR_VALID)

This register reflects the validity of the implicit read.

Figure 7-36. Reset Configuration Valid Register (RCR_VALID) (offset = B4h)



LEGEND: R = Read only; -*n* = value after reset

Table 7-38. Reset Configuration Valid Register (RCR_VALID) Field Descriptions

Bit	Field	Value	Description
31-2	Reserved	0	Reserved
1	JSM_VALID		When the L2FMC finishes the implicit read, it sets this bit to indicate that the contents of RCR_VALUE0 and RCR_VALUE1 are valid. This bit will be cleared in case there was a double-bit error during implicit reads.
		0	The implicit read has failed. The device level settings may not be correct.
		1	Implicit read is successful. Device level settings are correct.
0	RCR_VALID		When the L2FMC finishes the implicit read, it sets this bit to indicate that the contents of RCR_VALUE0 and RCR_VALUE1 are valid. This bit will be cleared in case there was a double-bit error during implicit reads.
		0	The implicit read has failed. The device level settings may not be correct.
		1	Implicit read is successful. Device level settings are correct.

7.10.27 Crossbar Access Time Threshold Register (ACC_THRESHOLD)

Figure 7-37. Crossbar Access Time Threshold Register (ACC_THRESHOLD) (offset = B8h)

LEGEND: R/W = Read/Write; R = Read only; WP = Write in Privilege Mode; -*n* = value after reset

Table 7-39. Crossbar Access Time Threshold Register (ACC_THRESHOLD) Field Descriptions

Bit	Field	Value	Description
31-12	Reserved	0	Reserved
11-0	ACC_THRESH_CNT	5FFh	Configures maximum number of clocks beyond which the L2FMC internal switch will timeout the access. This can occur due to soft error in internal logic. It is NOT recommended to modify this register unless a crossbar diagnostic is being performed.

Copyright © 2018, Texas Instruments Incorporated

7.10.28 Flash Error Detection and Correction Sector Disable Register 2 (FEDACSDIS2)

This register is used to disable the SECDED function on additional two sectors on the EEPROM Emulation Flash (bank 7).

Figure 7-38. Flash Error Detection and Correction Sector Disable Register 2 (FEDACSDIS2) (offset = C0h)

Table 7-45. FSM Sector Register 1 (FSM_SECTOR1) Field Descriptions

Bit	Field	Value	Description
31-0	SECT_ERASED		Sectors Erased. Each bit corresponds to a Flash sector in the bank specified by the FMAC register. Bit 0 corresponds to sector 0, bit 1 corresponds to sector 1, and so on.
		0	During bank erase, each sector whose corresponding bit is 0 will be erased. After bank erase, the bit corresponding to each sector that is erased will be changed from 0 to 1.
		1	During bank erase, each sector whose corresponding bit is 1 will not be erased.

NOTE: If the bank has less than 32 sectors, only those many LSB bits of FSM_SECTOR1 are valid. For EEPROM bank having more than 32 sectors, use this register in conjunction with FSM_SECTOR2.

7.10.34 FSM Sector Register 2 (FSM_SECTOR2)

This register is applicable to EEPROM bank having more than 32 sectors only. Refer to the device datasheet to find the number of EEPROM sectors in a particular device.

7.11 POM Control Registers

This section details the POM module registers listed in Table 7-48.

The POM module control registers can only be read and/or written while in privileged or debug mode. Each register begins on a word boundary. All registers are 32-bit, 16-bit and 8-bit accessible. The start address of the POM module is FFA0 4000h.

Table 7-48. POM Control Registers

Offset	Acronym	Register Description	Section
00h	POMGLBCTRL	POM Global Control Register	Section 7.11.1
04h	POM_REVID	POM Revision ID Register	Section 7.11.2
0Ch	POMFLG	POM Flag Register	Section 7.11.3
200h, 210h, ...	PROMPROGSTARTx	POM Region Start Address Register	Section 7.11.4

Level 2 RAM (L2RAMW) Module

This chapter describes the Level II RAM (L2RAM) module.

Topic **Page**

8.1 Overview **388**
8.2 Module Operation **388**
8.3 Control and Status Registers **393**

Copyright © 2018, Texas Instruments Incorporated

8.1 Overview

The Level 2 RAM (L2RAM) module controls and decodes RAM memory accesses on this device. Features of the L2RAM are:

- Controls read/write accesses to the data RAM
- Decodes addresses within the memory region allocated for the RAM
- Performs ECC check on all incoming CPU writes to ensure that data is intact
- Supports read and write accesses in 64-bit, 32-bit, 16-bit, or 8-bit access sizes
  - Performs redundant ECC check on merged data during read-modify-write operations
  - Does not support bit-wise operations
- Safety Features:
  - Single-Error-Correction Double-Error-Detection (SECDED) on data
    - Uses the CPU's Event bus and maintains the SECDED status in memory-mapped registers
    - Captures the number of occurrences of single-bit or multi-bit errors as well as the RAM address that has the fault
    - Generates error signals for single-bit and multi-bit errors to the Error Signaling Module (ESM)
  - Performs Memory Scrubbing to Identify and Correct Single Bit RAM errors in the L2RAM memory
  - SECDED Malfunction Checking to Verify that L2RAMW ECC is functioning correctly
  - Parity Protection of the Address Bus and Control Signals
    - Generates error signals for parity error to the Error Signaling Module (ESM)
  - Redundant Address Decode Scheme
    - Checks the decoding of CPU address lines and generation of correct memory selects for the RAM banks
- Exclusive access support
- Supports auto-initialization of the CPU data RAM banks
- Supports the RAM Trace Port (RTP) Interface
  - Traces out all RAM read and write accesses to the RTP module

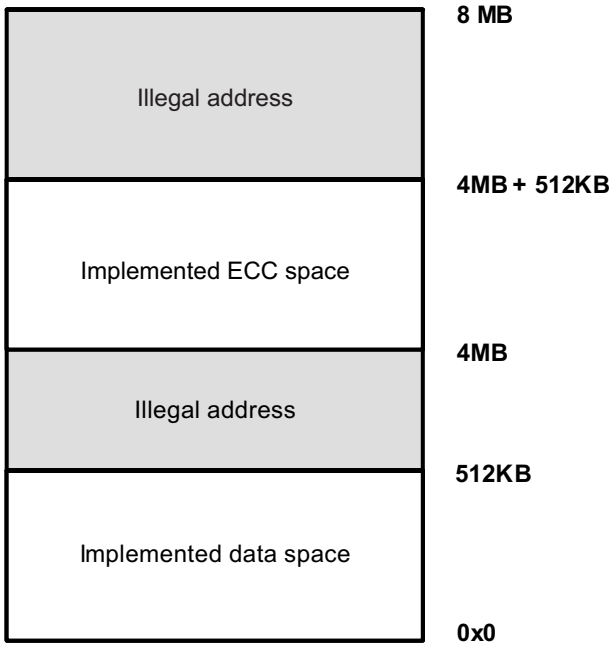
8.2 Module Operation

8.2.1 RAM Memory Map

The L2RAMW decodes 8MB of data space. Up to 512kB of implemented data space is supported. Check the specific part's datasheet to identify the actual amount of RAM supported on the device. This RAM is protected by ECC, allowing the CPU to correct any single-bit errors and detect multi-bit errors within a 64-bit value. The error correction code (ECC) values are stored in the RAM memory space as well. The memory map for the RAM and the corresponding ECC space is shown in Figure 8-1. Any access to an unimplemented RAM location results in an error response from the L2RAMW module.

Each RAM data word is 64-bits wide. These 64 bits are divided into 32 bits per RAM bank. The 8 bits of ECC are also divided into 4 bits per RAM bank.

For every 64-bit read from the RAM, an 8-bit ECC is also read by the CPU on its ECC bus. Similarly, for every 64-bit write to the RAM, the CPU also writes an 8-bit ECC using the same ECC bus.



The ECC memory can also be directly accessed via memory-mapped offset addresses. A read from the ECC space results in the 8-bit ECC value appearing on each byte of the 64-bit CPU data. Writes to ECC memory must be 64-bit aligned. Writes to the ECC space must also first be enabled via the RAM Control Register (RAMCTRL).

Accesses to the ECC space are not traced out to the RAM Trace Port (RTP).

Copyright © 2018, Texas Instruments Incorporated

NOTE: **No ECC Error Generated for Accesses to ECC Memory:** A read from the ECC memory itself would generate an ECC value on both the read data bus as well as the 8-bit ECC bus. This could result in the detection of a multi-bit error by the SECDED logic inside the CPU. The L2RAMW interface module ignores the ECC errors that are indicated by the CPU when accessing ECC space.

Figure 8-1. RAM Memory Map

8.2.2 Safety Features

The L2RAMW module incorporates some features that are designed specifically with safety considerations.

8.2.2.1 ECC Handling on 8-, 16-, and 32-Bit Writes

ECC calculation is handled by the R5F CPU except in the case of sub-64bit writes. If an 8-, 16-, or a 32-bit write is performed, L2RAMW handles the ECC calculation along with read-modify-write operation. This is to minimize the latency between CPU and L2RAMW in the case of sub-64bit write.

When a sub-64 bit write is performed with ECC enabled, the RAM Error Status Register flags any errors that are detected by the ECC logic of the L2RAMW.

NOTE: The RAM Error Status Register does not indicate ECC errors that are detected by the Cortex R5F CPU. These errors and handled and flagged in the R5F registers

Copyright © 2018, Texas Instruments Incorporated

8.2.2.2 Memory Scrubbing

To increase memory reliability, the L2RAMW has an optional "memory scrubbing" feature, which automatically corrects single bit errors whenever they are detected during any RAM read. The reason for performing this action is that if a single bit error occurs on the RAM, and no immediate action is taken to correct it, it is possible that a nearby bit cell will be corrupted as well at some point. If this were to occur, the two corrupted bits would result in a double-bit error that can no longer be corrected by the SECDED algorithm.

Memory scrubbing can be enabled by setting the Memory Scrubbing Enable (MSE) bit in the L2RAMW Module Control Register (RAMCTRL). Note that the ECC Detect Enable (ECC_DETECT_EN) field in RAMCTRL must be set to Ah before enabling memory scrubbing, since memory scrubbing uses the L2RAMW SECDED logic.

8.2.2.3 SECDED Malfunction

To enhance device safety, the L2RAMW has a SECDED malfunction detection feature to ensure that the SECDED logic is functioning correctly. Every time ECC is calculated for a CPU write data or a read data for a read-modify-write operation, the results of the ECC correction are compared back again to the original data value to ensure that the SECDED logic is working correctly. If an error in the SECDED logic is detected, it will be flagged in the RAMERRSTATUS Register (RAM Error Status).

8.2.2.4 L2RAMW Error Types and Responses

Table 8-1. L2RAMW Error Types

Error Source	Corresponding RAMERRSTATUS Bit	ESM Group
CPU Write ECC single error (correctable)	CPUWE (0)	Group 1
ECC double bit errors:		Group 3, bus error
Read-Modify-Write (RMW) ECC double bit error	RMWDE (7)	
CPU Write ECC double bit error	CPUWDE (5)	
Uncorrectable error Type A:		Group 3, bus error
Write SECDED malfunction error	WEME (3)	
Redundant address decode error	ADE (2)	
Read SECDED malfunction error	REME (1)	
Uncorrectable error Type B:		Group 2
Memory scrubbing SECDED malfunction error	MSSM (18)	
Memory scrubbing redundant address decode error	MSRA (17)	
Memory scrubbing address / control parity error	MSACP (16)	
ECC single bit and double bit diagnostic errors	DRDE(22), DRSE(21), DWDE(20), DWSE(19)	
Merged mux diagnostic error	MMDE (12)	
Write SECDED malfunction diagnostic error	WEMDE (11)	
Read SECDED malfunction diagnostic error	REMDE (10)	
Write data merged mux error	MME (9)	
Redundant address decode diagnostic error	ADDE (4)	
Command parity error on idle	CPEOI (15)	
Address / Control parity error	PACE(8)	Group 3, bus error
Level 2 RAM illegal address error	n/a	n/a (bus error only)
Memory initialization error	MIE (13)	n/a (bus error only)

8.2.2.5 Support for Cortex-R5F CPU's Address and Control Bus Parity Checking

The Cortex-R5F CPU provides parity bits for the address and control signals going to L2RAMW. The L2RAMW module also computes the parity bits based on the CPU's address bus and control signals. The computed parity bits are compared against the parity bits received from the CPU. A mismatch is recorded as Address/Control parity error (bit 8) in the RAMERRSTATUS register and signaled as an Address Parity Failure to the Error Signaling Module (ESM). It also generates a bus error.

The error flag in the RAMERRSTATUS register must be cleared by the application in order for the L2RAMW interface module to continue capturing subsequent errors and error addresses.

NOTE: **No Change Of Parity Scheme On-The-Fly:** The L2RAMW interface module does not support on-the-fly change to the parity scheme being used for checking the CPU address bus and control bus. The application must ensure that the parity polarity (odd or even) is not changed while there is an ongoing access to the L2RAM.

8.2.2.6 Redundant Address Decode

The L2RAMW module generates the memory selects for each of the L2RAMW banks as well as the ECC memory based on the CPU address. The logic to generate these memory selects is duplicated and the outputs compared to detect any address decode errors. A mismatch is indicated as an Address Error to the Error Signaling Module (ESM). The L2RAMW or ECC address that caused the fault is captured in the RAMUERRADDR register. This is a 64-bit address that is stored as an offset from the base of the L2RAMW or ECC memory.

As described earlier, each individual physical RAM bank is 36 bits wide. Each RAM bank contributes 32 bits of data and 4 bits of ECC when the bus master performs a 64-bit read from the L2RAM. Each L2RAMW bank receives a memory select and the address from the L2RAMW interface module. Any difference between the address and the memory selects results in wrong data and ECC pair being sent to the CPU. The CPU's SECDED block will detect this data error.

The L2RAMW interface module also supports a mechanism to test the operation of the redundant address decode logic and the compare logic. This testing is supported by providing a test stimulus, and can be triggered by the application by configuring the RAMTEST register. The address of any error identified during testing of the redundant address decode and compare logic is not captured in the RAMUERRADDR register.

NOTE: **Address decode checking when in compare logic test mode:** When the address decode and compare logic test mode is enabled, the redundant address decode and compare logic is not available for checking the proper generation of the memory selects for the L2RAMW and ECC memory.

Copyright © 2018, Texas Instruments Incorporated

8.2.3 L2RAMW Auto-Initialization

The RAM memory can be initialized by using the dedicated auto-initialization hardware. The L2RAMW module initializes the entire memory when the auto-init is enabled for the RAM. All RAM data memory is initialized to zeros and the ECC memory is initialized to the correct ECC value for zeros, that is, 0Ch.

8.2.4 Trace Module Support

The L2RAMW module traces out the following signals to the RAM Trace Port (RTP) module, thereby providing RAM dataport trace capability.

- 18-bit address line
- 64-bit data bus
- Byte strobe information
- Current access master identification number
- Access type: Opcode or data fetch
- Read or Write access

No data is traced for an access to ECC memory.

8.2.5 Emulation/Debug Mode Behavior

The following describes the behavior of the L2RAMW Module when in debug mode:

- No single-bit error interrupt is generated nor is any single-bit error address captured even when the RAMOCCUR counter reaches the programmed single-bit error correction threshold.
- No uncorrectable error interrupt is generated nor is any double-bit error address captured.
- No address parity error interrupt is generated nor is any parity error address captured.
- The RAMUERRADDR register is not cleared by a read in debug mode.
  - That is, if a double-bit error address is captured and is not read by the CPU before entering debug mode, then it remains frozen during debug mode even if it is read.
- The RAMPERRADDR register is not cleared by a read in debug mode.

8.2.6 Diagnostic Test Procedure

1. Write test vectors DIAG_DATA_VECTOR_H, DIAG_DATA_VECTOR_L, DIAG_ECC, and RAMADDRDEC_VECT with desire test irritants.
2. In RAMTEST, write TEST_ENABLE field with Ah and TEST_MODE field with the choice of inequality or equality testing for redundant address decoding and SECDED multifunction diagnostics. Set up proper values in DIAG_ECC, DIAG_DATA_VECTOR_L and DIAG_DATA_VECTOR_H registers. ECC single bit or double bit read and write diagnostic errors will be generated if the values do not match.
3. In RAMTEST, write TRIGGER bit. Remember the trigger can only be enabled when TEST_ENABLE is equal to Ah and RAMERRSTATUS[22,21,20,19,12,11,10, 4] bits are zero. Triggering diagnostic test while the memory banks are busy will force the test to wait until the banks are free. Note all diagnostic testing for two SECDEDs and compare logics of redundant address decode, two SECDED malfunctions, data merging block are completed in one HCLK cycle even though the TRIGGER bit can last one VCLK cycle.
4. Read back register bits RAMERRSTATUS[22,21,20,19,12,11,10, 4] and observe pass/fail status. No error bit will be set if no error is detected in the diagnostic test. The diagnostic errors will also be sent to ESM group 2 as "uncorrectable error type B".

8.3 Control and Status Registers

The L2RAMW Module registers listed in Table 8-2 are accessed through the system module register space in the Cortex-R5F CPUs memory map. All registers are 32-bit wide and are located on a 32-bit boundary. Reads and writes to registers are supported in 8-, 16-, and 32-bit accesses. The base address for the L2RAMW control registers is FFFF F900h.

Table 8-2. L2RAMW Module Control and Status Registers

Offset	Acronym	Register Description	Section
00h	RAMCTRL	L2RAMW Module Control Register	Section 8.3.1
10h	RAMERRSTATUS	L2RAMW Module Error Status Register	Section 8.3.2
24h	DIAG_DATA_VECTOR_H	Diagnostic Data Vector High Register	Section 8.3.3
28h	DIAG_DATA_VECTOR_L	Diagnostic Data Vector Low Register	Section 8.3.4
2Ch	DIAG_ECC	Diagnostic ECC Vector Register	Section 8.3.5
30h	RAMTEST	L2RAMW RAM Test Register	Section 8.3.6
38h	RAMADDRDEC_VECT	L2RAMW RAM Address Decode Vector Test Register	Section 8.3.7
3Ch	MEMINIT_DOMAIN	L2RAMW Memory Initialization Domain Register	Section 8.3.8

8.3.1 L2RAMW Module Control Register (RAMCTRL)

The RAMCTRL register, shown in Figure 8-2 and described in Table 8-3, controls the safety features supported by the L2RAMW Module.

Figure 8-2. L2RAMW Module Control Register (RAMCTRL) (offset = 00h)

31	30	29	28	27	24

Table 8-3. L2RAMW Module Control Register (RAMCTRL) Field Descriptions

Bit	Field	Value	Description
31	Reserved	0	Reads return 0. Writes have no effect.
30	EMU_TRACE_DIS		Emulation Mode Trace Disable. This bit, when set, disables the tracing of read data to RAM Trace Port (RTP) module during emulation mode access.
		0	Data is allowed to be traced out to the trace modules for emulation mode accesses.
		1	Data is blocked from being traced out to the trace modules for emulation mode accesses.
29-28	Reserved	0	Reads return 0. Writes have no effect.

Copyright © 2018, Texas Instruments Incorporated

Table 8-3. L2RAMW Module Control Register (RAMCTRL) Field Descriptions (continued)

Bit	Field	Value	Description
27-24	ADDR_PARITY_OVERRIDE		Address Parity Override. This field, when set to Ah, will invert the parity scheme selected by the device global parity selection. The address parity checker would then work on the inverted parity scheme. By default, the parity scheme is the same as the global device parity scheme.
		Ah	Parity scheme is opposite to the device global parity scheme.
		All other values	Parity scheme is the same as the device global parity scheme.
23-21	Reserved	0	Reads return 0. Writes have no effect.
20	MSE		MSE: Memory Scrubbing Enable. This bit enables or disables memory scrubbing of single-bit errors on read operations.
			Note: The ECC_DETECT_EN field must be set to Ah before enabling memory scrubbing, since memory scrubbing uses the L2RAMW SECDED logic.
		0	Memory scrubbing is disabled.
		1	Memory scrubbing is enabled.
19-16	ADDR_PARITY_DISABLE		Address/Control Bus Parity Detect Disable. This field, when set to Ah, disables the parity checking for the address and control bus. The parity checking is enabled when this field is set to any other value.
			Note: The application must ensure that PACE field in RAMERRSTATUS register is cleared before enabling address/control bus parity checking.
		Ah	Address parity checking is disabled.
		All other values	Address parity checking is enabled.
15-13	Reserved	0	Reads return 0. Writes have no effect.
12	EEMMS		Enable ESM notification (Parity, Redundant Address Decode, SECDED malfunction) for write back during memory scrubbing.
		0	ESM will not be signaled when an error occurs during memory scrubbing write back.
		1	ESM will be signaled when an error occurs during memory scrubbing write back.
11-9	Reserved	0	Reads return 0. Writes have no effect.
8	ECC_WR_EN		ECC Memory Write Enable. This bit is provided to prevent accidental writes to the ECC memory. A write access to the ECC memory is allowed only when the ECC_WR_EN bit is set to 1. If this bit is cleared, then any writes to ECC memory are ignored.
			Note: Reads are allowed from the ECC memory regardless of the state of the ECC_WR_EN.
		0	ECC memory writes are disabled.
		1	ECC memory writes are enabled.
7-5	Reserved	0	Reads return 0. Writes have no effect.
4	CPUWSC		CPUWSC: CPU Write SERR Capture. By default, single bit error are not signaled to ESM module. This bit allows the option to capture the status and notify ESM.
			Note: This feature is only applicable to CPU write data.
		0	Disable single bit error status capture and ESM notification.
		1	Enable single bit error status capture and ESM notification.
3-0	ECC_DETECT_EN		ECC Detect Enable. This is a 4-bit key to enable the ECC detection feature in the L2RAMW Module. Error detection, status updates, and data correction are performed by the L2RAMW logic only if ECC detection is enabled. ECC detection is enabled by default after reset.
			Note: Disabling ECC on the L2RAMW module will disable ECC error checking only for the ECC functions that the L2RAM handles (sub 64-bit Write Operations). All other ECC handling is done by the R5F CPU. ECC error checking cannot be disabled on the R5F CPU.
		5h	ECC detection is disabled.
		All other values	ECC detection is enabled.

Table 8-4. L2RAMW Module Error Status Register (RAMERRSTATUS) Field Descriptions

Bit	Field	Value	Description
31-23	Reserved	0	Reads return 0. Writes have no effect.
22	DRDE		Diagnostic Read Double-bit Error. This bit indicates that a double-bit error has occurred during diagnostic of the L2RAMW SECDED logic that is used to handle read of read-modify write operations. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	A double-bit error did not occur during diagnostic.
		1	A double-bit error occurred during diagnostic.
21	DRSE		Diagnostic Read Single-bit Error. This bit indicates that a single-bit error has occurred during diagnostic of the L2RAMW SECDED logic that is used to handle read of read-modify write operations. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	A single-bit error did not occur during diagnostic.
		1	A single-bit error occurred during diagnostic.
20	DWDE		Diagnostic Write Double-bit Error. This bit indicates that a double-bit error has occurred during diagnostic of the L2RAMW SECDED logic that handles write operations. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	A double-bit error did not occur during diagnostic.
		1	A double-bit error occurred during diagnostic.
19	DWSE		Diagnostic Write Single-bit Error. This bit indicates that a single-bit error has occurred during diagnostic of the L2RAMW SECDED logic that handles write operations. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	A single-bit error did not occur during diagnostic.
		1	A single-bit error occurred during diagnostic.
18	MSSM		Memory Scrubbing write back SECDED Malfunction. This indicates that a SECDED malfunction occurred during memory scrubbing write back. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	A SECDED malfunction did not occur during scrubbing write back.
		1	A SECDED malfunction occurred during scrubbing write back.
17	MSRA		Memory Scrubbing write back Redundant Address decode error. This bit indicates that a redundant address decode error occurred during memory scrubbing write back. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An address decode error did not occur during scrubbing write back.
		1	An address decode error occurred during scrubbing write back.

Copyright © 2018, Texas Instruments Incorporated

Table 8-4. L2RAMW Module Error Status Register (RAMERRSTATUS) Field Descriptions (continued)

Bit	Field	Value	Description
16	MSACP		Memory Scrubbing write back Redundant Address decode error. This bit indicates that an address-control parity error occurred during memory scrubbing write back. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An address control parity error did not occur during memory scrubbing write back.
		1	An address control parity error occurred during memory scrubbing write back.
15	CPEOI		Command Parity Error on Idle. This bit indicates an error occurred for an idle command with parity error. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
14	Reserved	0	Reads return 0. Writes have no effect.
13	MIE		Memory Initialization Error. This bit indicated an error occurred for an access to a bank under memory initialization. Access to a bank under memory initialization is not allowed. It will result in a false double bit error. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
12	MMDE		Merged MUX Diagnostic Error. This bit indicates a error was detected on the compare logic of the mux logic used for data merging of a read modify write operation during diagnostic test. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
11	WEMDE		Write ECC Malfunction Diagnostic Error. This bit indicated an error was detected on the compare logic of the write ECC malfunction during diagnostic test. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
10	REMDE		Read ECC Malfunction Diagnostic Error. This bit indicated an error was detected on the compare logic of the read ECC malfunction during diagnostic test. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
9	MME		Merged Mux Error. This bit indicates an error was detected on the mux logic that is used to merge the corrected read and write data for a read modify write operation. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
8	PACE		Address and/or Control bus Parity Error. This bit must cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
7	RMWDE		Read-Modify-Write Double Bit Error. This bit indicates that an ECC uncorrectable (double bit) error was detected during read access of the read modify write operation. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
6	Reserved	0	Reads return 0. Writes have no effect.
5	CPUWDE		CPU Write Double-bit Error. This bit indicates that an ECC uncorrectable (double bit) error was detected during write access. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.

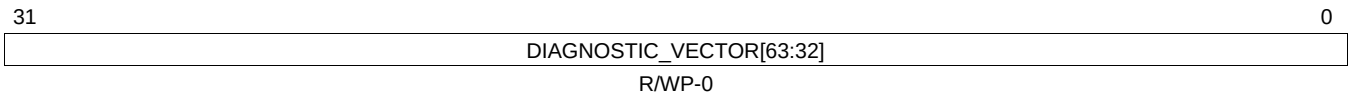
Table 8-4. L2RAMW Module Error Status Register (RAMERRSTATUS) Field Descriptions (continued)



Bit	Field	Value	Description
4	ADDE		Redundant address decoding diagnostic error. This bit indicates that the redundant address decode logic diagnostic test has detected that a compare element has malfunctioned during the testing of the logic. This bit is only set in test mode. This bit must be cleared by writing a 1 to it for generation of any new uncorrectable error interrupt in non-test mode.
		0	An error did not occur.
		1	An error occurred.
3	WEME		Write ECC Malfunction Error. This bit Indicates that the SECDED logic failed to correct a single bit error during a CPU write operation. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
2	ADE		Address Decode Error. This bit indicates than an address error was generated by the redundant address decode logic due to a functional failure. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
1	REME		Read ECC Malfunction Error. Indicates that the SECDED logic failed to correct a single bit error on the read of a read-modify-write operation. This bit must be cleared by writing a 1 to it before any new error can be generated.
		0	An error did not occur.
		1	An error occurred.
0	CPUWE		CPU Write Single Error. This bit indicates that a single-bit error occurred during write access. This bit must be cleared by writing 1 to it in order to clear the interrupt request and to enable subsequent single-bit error interrupt generation.
		0	An error did not occur.
		1	An error occurred.

8.3.3 L2RAMW Diagnostic Data Vector High Register (DIAG_DATA_VECTOR_H)

The DIAG_DATA_VECTOR_H register, shown in Figure 8-4 and described in Table 8-5, is used in conjunction with the RAMTEST register to perform diagnostic tests.

Figure 8-4. L2RAMW Diagnostic Data Vector High Register (DIAG_DATA_VECTOR_H) (offset = 24h)

LEGEND: R/W = Read/Write; WP = Write in privilege mode only; -*n* = value after reset

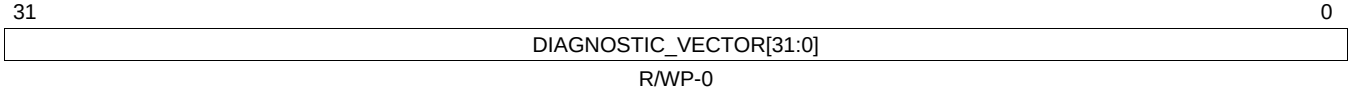

Table 8-5. L2RAMW Diagnostic Data Vector High Register (DIAG_DATA_VECTOR_H) Field Descriptions

Bit	Field	Description
31-0	DIAGNOSTIC_VECTOR	Used in conjunction with DIAG_DATA_VECTOR_L to form a 64-bit test vector used for diagnostic test of two SECDEDs (read and write) and compare logic of the two SECDED malfunctions and merged mux. This register is the upper 32 bits. This register is used in conjunction with the RAMTEST register to perform diagnostic tests. See Section 8.2.6 for details on how to start a diagnostic test.

8.3.4 L2RAMW Diagnostic Data Vector Low Register (DIAG_DATA_VECTOR_L)

The DIAG_DATA_VECTOR_L, shown in Figure 8-5 and described in Table 8-6, is used in conjunction with the RAMTEST register to perform diagnostic tests.

Figure 8-5. L2RAMW Diagnostic Vector Low Register (DIAG_DATA_VECTOR_L) (offset = 28h)

LEGEND: R/W = Read/Write; WP = Write in privilege mode only; -*n* = value after reset

Table 8-7. L2RAMW Diagnostic ECC Vector Register (DIAG_ECC) Field Descriptions

Bit	Field	Value	Description
31-8	Reserved	0	Reads return 0. Writes have no effect.
7-0	DIAG_ECC_VECTOR	0-FFh	Diagnostic ECC Vector. This field provides an 8-bit ECC test vector used for diagnostic test of the two SECDEDs and compare logic for two SECDED malfunctions and merged mux. This register is used in conjunction with DIAG_DATA_VECTOR_H and DIAG_DATA_VECTOR_L registers to form a data/ECC pair in the diagnostic ECC checking test. See Section 8.2.6 for details on how to start a diagnostic test.

Copyright © 2018, Texas Instruments Incorporated

8.3.6 L2RAMW RAM Test Mode Control Register (RAMTEST)

The RAMTEST register, shown in Figure 8-7 and described in Table 8-8, controls the test mode of the L2RAMW Module.

Figure 8-7. L2RAMW Module Test Mode Control Register (RAMTEST) (offset = 30h)

31	16
Reserved	
R-0	

15	9	8	7	6	5	4	3	0
Reserved		TRIGGER	TEST_MODE		Reserved		TEST_ENABLE	
R-0		R/WP-0	R/WP-0		R-0		R/WP-5h	

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 8-8. L2RAMW Module Test Mode Control Register (RAMTEST) Field Descriptions

Bit	Field	Value	Description
31-9	Reserved	0	Reads return 0. Writes have no effect.
8	TRIGGER		Test Trigger. This is an auto clear test trigger used to test the redundant address decode, data merging mux, SECDED malfunction compare logic, and ECC checking logics. The diagnostic test is executed when test mode is enabled and the test trigger is applied by writing a 1 to this bit. The trigger is valid only if test mode is enabled, the correct mode is configured in the TEST_MODE field, and all diagnostic error bits in the RAMERRSTATUS register are in the cleared state. The trigger bit is auto clear after the test and has to be written again for a new test.
7-6	TEST_MODE		Test Mode. This field selects either equality or inequality testing schemes for redundant address decoding and SECDED malfunction diagnostics. If TEST_MODE is set to 2h, equality check is done. The test stimulus stored in RAMADDRDEC_VECT register is fed directly to both the channels of the comparator. If the XOR of these two inputs **is not zero**, then UERR interrupt is generated and ADDE flag is set in RAMERRSTATUS register. If TEST_MODE is set to 1h, inequality check is done. The test stimulus stored in RAMADDRDEC_VECT register is inverted and fed into one channel and the non-inverted vector is fed into the other channel. If the XOR of these inputs **is zero**, then the UERR interrupt is generated and ADDE flag is set in RAMERRSTATUS register.
5-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	TEST_ENABLE		Test Enable. This is a 4-bit key to enable the redundant address decode, SECDED malfunction, data merging mux and ECC checking diagnostics. If the test scheme is enabled, then the compare logic uses the test vector inputs from the RAMADDRDEC_VECT, DIAG_ECC, DIAG_DATA_VECTOR_L, and DIAG_DATA_VECTOR_H registers. The functional path comparison is disabled when test mode is enabled.
		Ah	Test mode is enabled.
		All other values	Test mode is disabled.

8.3.7 L2RAMW RAM Address Decode Vector Test Register (RAMADDRDEC_VECT)

The RAMADDRDEC_VECT register, shown in Figure 8-8 and described in Table 8-9, is used for testing the redundant address decode and compare logic of the L2RAMW Module.

Figure 8-8. L2RAMW RAM Address Decode Vector Test Register (RAMADDRDEC_VECT) (offset = 38h)

Bit	Field	Value	Description
31-8	Reserved	0	Reads return 0. Writes have no effect.
7-0	MEMINIT_ENA[*n*]		Memory Initialization Enable. Each bit *n* corresponds to an individual memory domain. If the corresponding bit is set to 1 when an initialization of the RAM memory is executed, then that section of the RAM memory will be initialized. If the corresponding bit is cleared to 0 when an initialization of the RAM memory is executed, then that section of the RAM memory will not be affected. After reset, all memory power domains are enabled (set to 1) by default.
			Bit 0: enable bit for power domain 0.
			Bit 1: enable bit for power domain 1.
			:
			Bit 7: enable bit for power domain 7.
		1	Enable the memory in this power domain to be initialized.
		0	Disable the memory in this power domain from being initialized.

Programmable Built-In Self-Test (PBIST) Module

This chapter describes the programmable built-in self-test (PBIST) controller module used for testing the on-chip memories.

Topic **Page**

9.1 Overview 406
9.2 RAM Grouping and Algorithm 407
9.3 PBIST Flow 408
9.4 Memory Test Algorithms on the On-chip ROM 411
9.5 PBIST Control Registers 412
9.6 PBIST Configuration Example 426

Copyright © 2018, Texas Instruments Incorporated

9.1 Overview

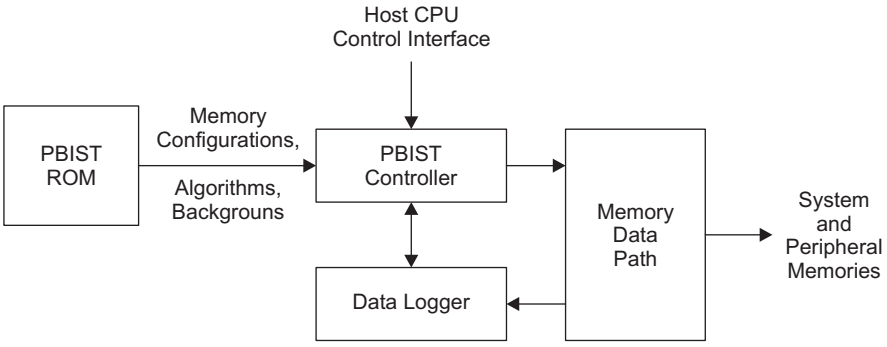
The PBIST (Programmable Built-In Self-Test) controller architecture provides a run-time-programmable memory BIST engine for varying levels of coverage across many embedded memory instances.

9.1.1 Features of PBIST

- Information regarding on-chip memories, memory groupings, memory background patterns and test algorithms stored in dedicated on-chip PBIST ROM
- Host processor interface to configure and start BIST of memories
- Supports testing of PBIST ROM itself as well
- Supports testing of each memory at its maximum access speed in application
- Implements intelligent clock gating to conserve power
- Execution of microcode from PBIST ROM supported for ROM clock speeds up to 100 MHz

9.1.2 PBIST vs. Application Software-Based Testing

The PBIST architecture consists of a small coprocessor with a dedicated instruction set targeted specifically toward testing memories. This coprocessor executes test routines stored in the PBIST ROM and runs them on multiple on-chip memory instances. The on-chip memory configuration information is also stored in the PBIST ROM.



The PBIST Controller architecture offers significant advantages over tests running on the main Cortex-R5F processor (application software-based testing):

- Embedded CPUs have a long access path to memories outside the tightly-couple memory sub-system, while the PBIST controller has a dedicated path to the memories specifically for the self-test
- Embedded CPUs are designed for their targeted use and are often not easily programmed for memory test algorithms.
- The memory test algorithm code on embedded CPUs is typically significantly larger than that needed for PBIST.
- The embedded CPU is significantly larger than the PBIST controller.

9.1.3 PBIST Block Diagram

Figure 9-1 illustrates the basic PBIST blocks and its wrapper logic for the device.

Figure 9-1. PBIST Block Diagram

Copyright © 2018, Texas Instruments Incorporated

9.1.3.1 On-chip ROM

The on-chip ROM contains the information regarding the algorithms and memories to be tested.

9.1.3.2 Host Processor Interface to the PBIST Controller Registers

The Cortex-R5F CPU can select the algorithm and RAM groups for the memories' self-test from the on-chip ROM based on the application requirements. Once the self-test has executed, the CPU can query the PBIST controller registers to identify any memories that failed the self-test and to then take appropriate next steps as required by the application's author.

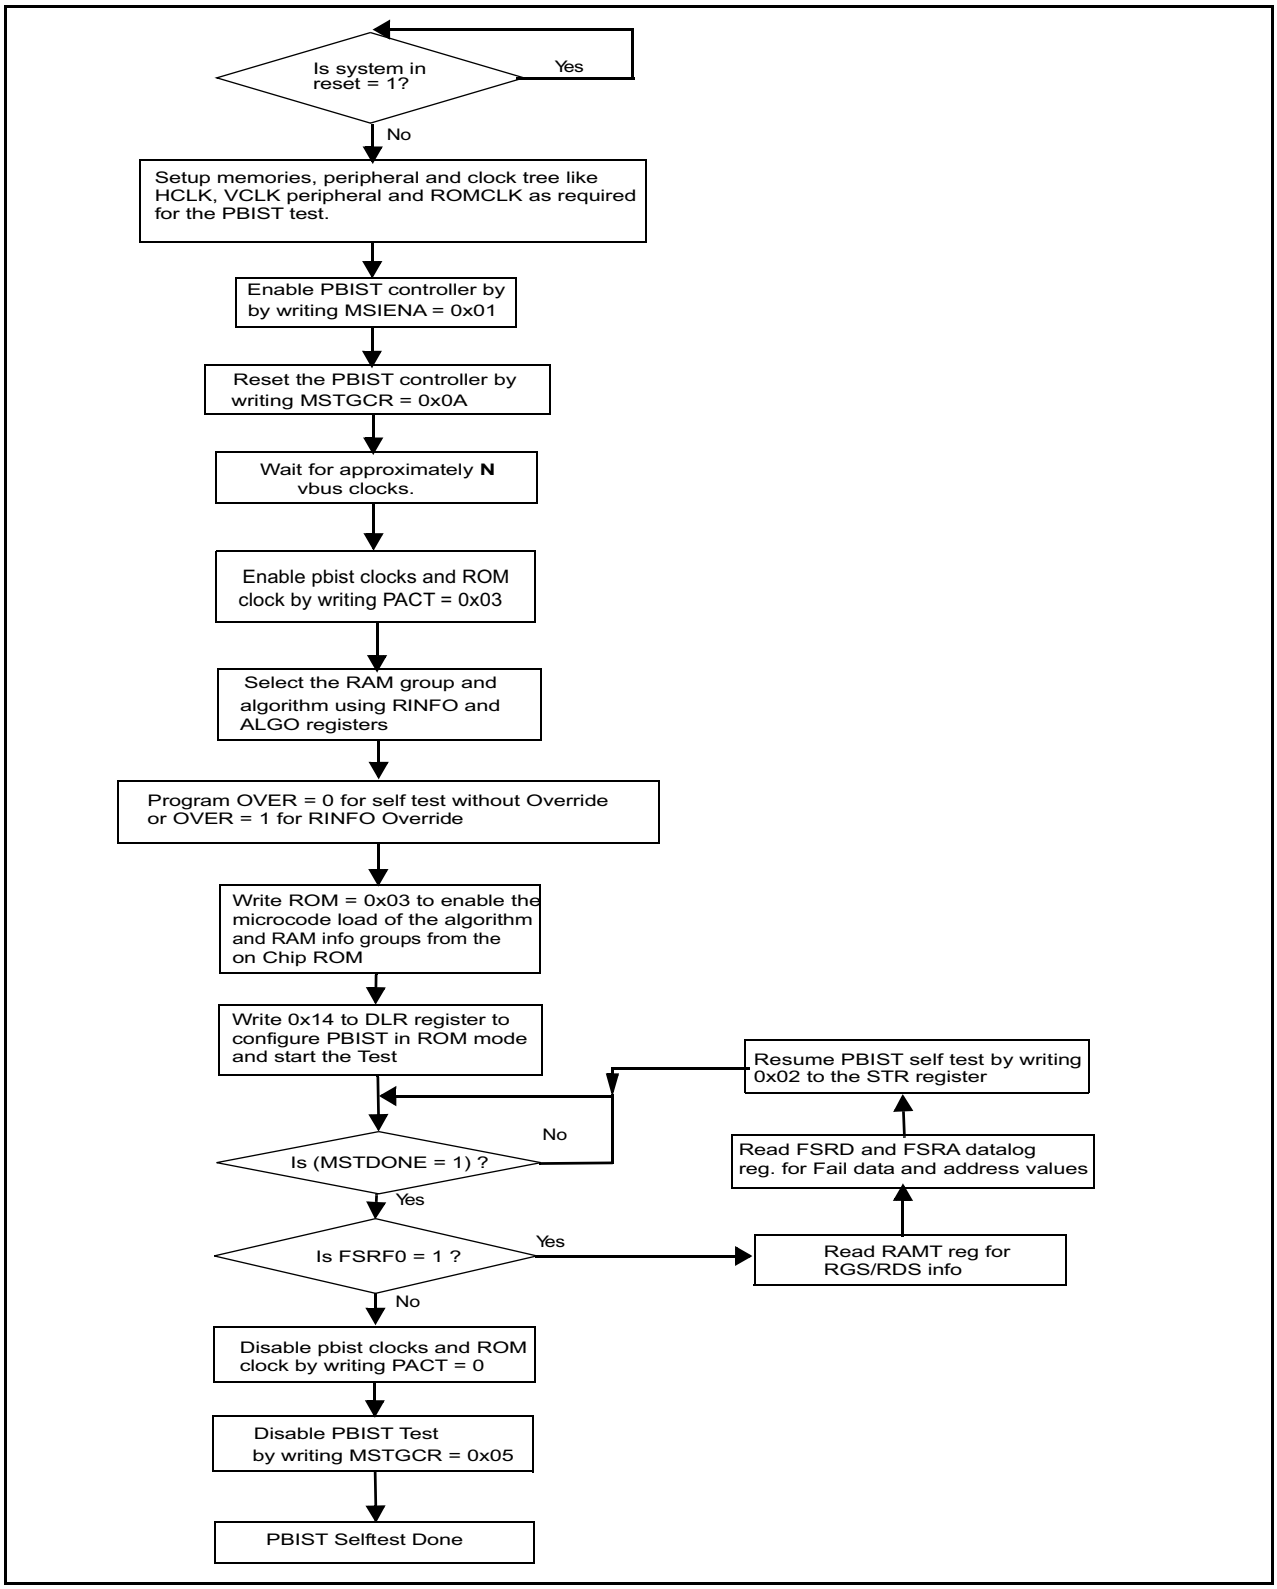
9.1.3.3 Memory Data Path

This is the read and write data path logic between different system and peripheral memories tightly coupled to the PBIST memory interface. The PBIST controller executes each selected algorithm on each valid memory group sequentially until all the algorithms are executed.

NOTE: Not all algorithms are designed to run on all RAM groups. If an algorithm is selected to run on an incompatible memory, this will result in a failure. Refer to Table 2-5 and Table 2-6 for RAM grouping and algorithm information.

9.2 RAM Grouping and Algorithm

Table 2-5 gives the list of RAM groups and their types supported on the device. Table 2-6 maps the different algorithms supported in application mode for the RAM groups with the background patterns used for the particular algorithm.



NOTE: March13 is the most recommended algorithm for the memory self-test.

9.3 PBIST Flow

Figure 9-2 illustrates the memory self-test flow.

Figure 9-2. PBIST Memory Self-Test Flow Diagram

Copyright © 2018, Texas Instruments Incorporated

9.3.1 PBIST Sequence

Before starting the PBIST sequence, you should ensure that both the instruction cache and data cache are disabled. By default, PBIST will test all on-chip SRAMs including both the instruction and data cache memories. After reset, cache is disabled by default. If cache has been enabled, use the following code example to disable the cache.

```
MRC   p15, #0, R1, c1, c0, #0   ; Read System Control Register configuration data
BIC   R1, R1, #0x1 <<12         ; instruction cache disable
BIC   R1, R1, #0x1 <<2          ; data cache disable
DSB
MCR   p15, #0, R1, c1, c0, #0   ; disabled cache RAMs ISB
```

1. Configure the device clock sources and domains so that they are running at their target frequencies.
2. Program the GCLK1 to PBIST ROM clock ratio by configuring the ROM_DIV field (bits 9:8) of the MSTGCR register of the system module. This device supports a max PBIST ROM clock frequency of 82.5MHz.
3. Enable PBIST Controller by setting bit 1 of MSIENA register in system module.
4. Enable the PBIST self-test by writing a value of 0x0A to bits 3:0 of the MSTGCR in the system module.
5. Wait for N VBUS clock cycles based on the HCLK to PBIST ROM clock ratio:

   N = 16 when GCLK1:PBIST ROM clock is 1:1
   N = 32 when GCLK1:PBIST ROM clock is 1:2
   N = 64 when GCLK1:PBIST ROM clock is 1:4
   N = 64 when GCLK1:PBIST ROM clock is 1:8
6. Write 1h to PACT register to enable the PBIST internal clocks.
7. Program the ALGO register to decide which algorithm from the instruction ROM must be selected (the default value of ALGO register is all 1's, meaning all algorithms are selected). Similarly, program the RINFOL and RINFOU registers to indicate whether a particular RAM group in the instruction ROM would get executed or not.

   NOTE: In case of RAM Override (Override Register (OVER) = 00), the user should make sure that only the algorithms that run on similar RAMs are selected. If a single port algorithm is selected in ROM Algorithm Mask Register (ALGO), the RAM Info Mask Lower Register (RINFOL) and RAM Info Mask Upper Register (RINFOU) must select only the single port RAM's. The same applies for two port RAM's. Check Table 2-5 for information on the memory types.
8. Program OVER = 1h to run PBIST self-test without RAM override. Program OVER = 0 to run PBIST self-test with RAM Override.
9. Write a value of 3h to the ROM mask register should the microcode for the Algorithms as well as the RAM groups loaded from the on-chip PBIST ROM.
10. Write DLR (Data Logger register) with 14h to configure the PBIST run in ROM mode and to enable the configuration access. This starts the memory self-tests.
11. Wait for the PBIST self-test done by polling MSTDONE bit of MSTCGSTAT register in System Module.
12. Once self-test is completed, check the Fail Status register FSRF0.

    In case there is a failure (FSRF0 = 1h):
    a. Read RAMT register that indicates the RGS and RDS values of the failure RAM.
    b. Read FSRC0 and FSRC1 registers that contain the failure count.
    c. Read FSRA0 and FSRA1 registers that contain the address of first failure.
    d. Read FSRDL0 and FSRDL1 registers that contain the failure data.
    e. Write a value of 2h to the STR register to resume the test.

    In case there is no failure (FSRF0 = 0), the memory self-test is completed.
    a. Disable the PBIST internal clocks by writing a 0 to the PACT register.
    b. Disable the PBIST self-test by writing a value of 5h to bits 3:0 of the MSTGCR in the system module.

Copyright © 2018, Texas Instruments Incorporated

13. Repeat steps 2 through 9 for subsequent runs with different RAM group and algorithm configurations.
14. After required Memory tests are completed, Resume or Start the Normal Application software.

NOTE: The contents of the selected memory before the test will be completely lost. User software must take care of data backup if required. Typically the PBIST tests are carried out at the beginning of Application software.

NOTE: Memory test fail information is reported in terms of RGS:RDS and not RAM GROUP. Check Table 2-5 for information on the RGS:RDS information applicable to each memory being tested.

If cache memory is selected to be part of the PBIST test then the contents will become incoherent with respect to the level 2 memory after the PBIST test. The cache will need to be invalidated before cache can be enabled for use by the CPU. In addition, if you are using ECC error checking scheme in the cache, you must enable this by programming the CEC bits in the Auxiliary Control Register before invalidating the cache, to ensure that the correct error code bits are calculated when the cache is invalidated. For more information on the CEC bits in the Auxiliary Control Register, refer to the ARM® Cortex®-R5F Technical Reference Manual.

Use the following example code to invalidate cache and enable cache.

```
MRC p15, #0, R1, c1, c0, #1   ; Read auxiliary control register
BIC R1, R1, #0x1, <<5         ; bit is default set to disable ECC. Clearing bit 5
MCR p15, #0, R1, c1, c0, #1   ; enable ECC, generate abort on ECC errors, enable
                              ; hardware recovery
MRC p15, #0, R1, c1, c0, #0   ; Read system control register configuration data
ORR R1, R1, #0x1 <<12         ; instruction cache enable
ORR R1, R1, #0x1 <<2          ; data cache enable
DSB
MCR p15, #0, R0, c15, c5, #0  ; invalidate entire data cache
MCR p15, #0, R0, c7, c5, #0   ; invalidate entire instruction cache
MCR p15, #0, R1, c1, c0, #0   ; enable cache RAM
ISB                           ; You must issue an ISB instruction to flush the pipeline.
                              ; This ensures that all subsequent instruction fetches
                              ; see the effect of enabling the instruction cache
```

9.4 Memory Test Algorithms on the On-chip ROM

This section provides a brief description for some of the test algorithms used for memory self-test.

1. **March13N:**
   - March13N is the baseline test algorithm for SRAM testing. It provides the highest overall coverage. The other algorithms provide additional coverage of otherwise missed boundary conditions of the SRAM operation.
   - The concept behind the general march algorithm is to indicate:
     – The bit cell can be written and read as both a 1 and a 0.
     – The bits around the bit cell do not affect the bit cell.
   - The basic operation of the march is to initialize the array to a know pattern, then march a different pattern through the memory.
   - Type of faults detected by this algorithm:
     – Address decoder faults
     – Stuck-At faults
     – Coupled faults
     – State coupling faults
     – Parametric faults
     – Write recovery faults
     – Read/write logic faults

Copyright © 2018, Texas Instruments Incorporated

9.5 PBIST Control Registers

PBIST controller uses configuration registers for programming the algorithm and its execution. All the configuration registers are memory mapped for access by the CPU through the Peripheral Bus interface. The base address for the control registers is FFFF E400h.

NOTE: There is no watchdog functionality implemented in the PBIST controller. If a bad code is executed, the PBIST runs forever. The PBIST controller does not guard against this situation.

Registers are accessible only when the clock to the PBIST controller is active. The clock is activated by first writing 1h to the PACT register.

Table 9-1. PBIST Registers

Offset	Acronym	Register Description	Section
160h	RAMT	RAM Configuration Register	Section 9.5.1
164h	DLR	Datalogger Register	Section 9.5.2
180h	PACT	PBIST Activate/Clock Enable Register	Section 9.5.3
184h	PBISTID	PBIST ID Register	Section 9.5.4
188h	OVER	Override Register	Section 9.5.5
190h	FSRF0	Fail Status Fail Register 0	Section 9.5.6

9.5.1 RAM Configuration Register (RAMT)

This register is divided into following internal registers, none of which have a default value after reset. Figure 9-3 and Table 9-2 illustrate this register.

This register provides the information regarding the memory being currently tested. In case of a PBIST failure, the application can read this register to identify the RGS:RDS values for the memory that failed the self-test.

Figure 9-3. RAM Configuration Register (RAMT) [offset = 0160h]

31	24	23	16
RGS		RDS	
R/W-X		R/W-X	

15	8	7	6	5	2	1	0

R/W-X		R/W-X		R/W-X		R/W-X	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 9-2. RAM Configuration Register (RAMT) Field Descriptions

Bit	Field	Description
31-24	RGS	Ram Group Select. Refer to Table 2-5 for information on the RGS value for each memory.
23-16	RDS	Return Data Select. Refer to Table 2-5 for information on the RDS values for each memory. **Note:** In the current version of the PBIST, only 5 bits are used for RDS.
15-8	DWR	Data Width Register
7-6	SMS	Sense Margin Select Register
5-2	PLS	Pipeline Latency Select
1-0	RLS	RAM Latency Select

Copyright © 2018, Texas Instruments Incorporated

9.5.2 Datalogger Register (DLR)

This register puts the PBIST controller into the appropriate comparison modes for data logging. Figure 9-4 and Table 9-3 illustrate this register.

Figure 9-4. Datalogger Register (DLR) [offset = 0164h]

31	16
Reserved	
R-0	

15	5	4	3	2	1	0
Reserved		DLR4	Rsvd	DLR2	Reserved	
R-0		R/W-0	R/W-1	R/W-0	R/W-0	

LEGEND: R/W = Read/Write; R = Read only; *-n* = value after reset

Table 9-3. Datalogger Register (DLR) Field Descriptions

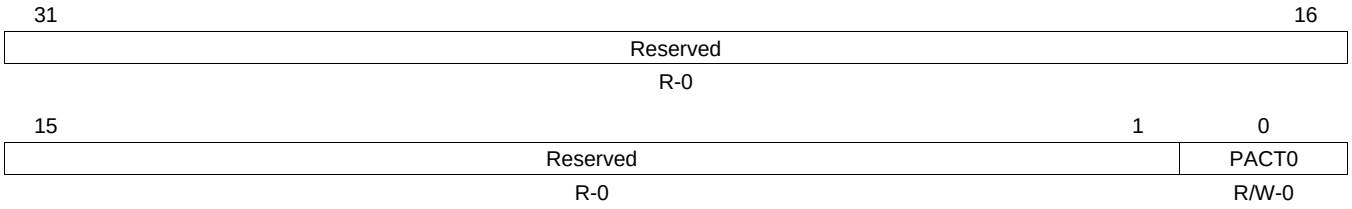
Bit	Field	Value	Description
31-5	Reserved	0	Reads return 0. Do not change these bits from their default value.
4	DLR4		Config access: setting this bit allows the host processor to configure the PBIST controller registers.
3	Reserved	1	Do not change this bit from its default value of 1.
2	DLR2		ROM-based testing: setting this bit enables the PBIST controller to execute test algorithms that are stored in the PBIST ROM.
1-0	Reserved	00	Do not change these bits from their default value of 00.

- **DLR2: ROM-based testing mode**

Writing a 1 to this register starts the ROM-based testing. This register is used to initiate ROM-based testing from Config and ATE interfaces. Also, since a 1 in this bit position means the instruction ROM is used for memory testing, all the intermediate interrupts and PBIST done signal after each memory test are masked until all the selected algorithms in the ROM are executed for all RAM groups. However, a failure would stop the test and report the status immediately.

- **DLR4: Config access mode**

This mode, when set, indicates the CPU is being used to access PBIST.



Copyright © 2018, Texas Instruments Incorporated

9.5.3 PBIST Activate/Clock Enable Register (PACT)

This is the first register that needs to be programmed to activate the PBIST controller. Bit [0] is used for static clock gating, and unless a 1 is written to this bit, all the internal PBIST clocks are shut off. Figure 9-5 and Table 9-4 illustrate this register.

NOTE: This register must be programmed to 1h during application self-test.

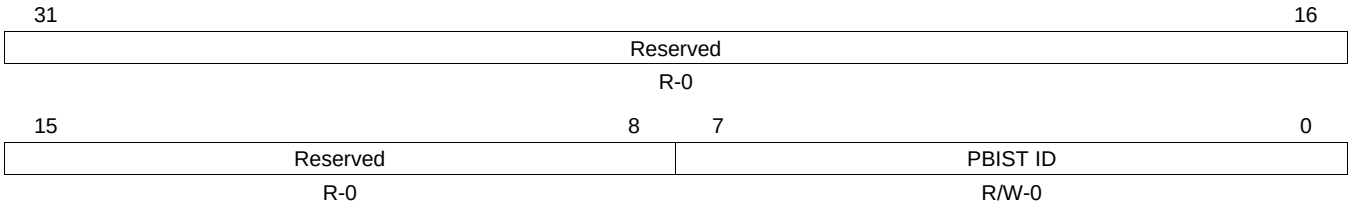
Figure 9-5. PBIST Activate/ROM Clock Enable Register (PACT) [offset = 0180h]

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 9-4. PBIST Activate/ROM Clock Enable Register (PACT) Field Descriptions

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	PACT0		PBIST internal clocks enable.
		0	Disable PBIST internal clocks.
		1	Enable PBIST internal clocks.

- **PACT0**



This bit must be set to 1 to turn on the PBIST internal clocks. Setting this bit asserts an internal signal that is used as the clock gate enable. As long as this bit is 0, any access to the PBIST will not go through and the PBIST will remain in an almost zero-power mode.

Copyright © 2018, Texas Instruments Incorporated

9.5.4 PBIST ID Register

Functionality of the register is described in Figure 9-6 and Table 9-5.

Figure 9-6. PBIST ID Register [offset = 184h]

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 9-5. PBIST ID Register Field Descriptions

Bit	Field	Value	Description
31-8	Reserved	0	Reads return 0. Writes have no effect.
7-0	PBIST ID		This is a unique ID assigned to each PBIST controller in a device with multiple PBIST controllers.

Copyright © 2018, Texas Instruments Incorporated

9.5.5 Override Register (OVER)

Functionality of the register is described in Figure 9-7 and Table 9-6.

Figure 9-7. Override Register (OVER) [offset = 0188h]

31	16
Reserved	
R-0	

15	3	2	1	0
Reserved		Reserved		OVER0
R-0		R-0		R/W-1

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 9-6. Override Register (OVER) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reads return 0. Writes have no effect.
2-1	Reserved	0	Reserved. This bit must not be changed from its default value of 0.
0	OVER0		RINFO Override Bit
		0	The RAM info registers RINFOL and RINFOU are used to select the memories for test.
		1	The memory information available from ROM will override the RAM selection from the RAM info registers RINFOL and RINFOU.

- **OVER0**

While doing ROM-based testing, each algorithm downloaded from the ROM has a memory mask associated with it that defines the applicable memory groups the algorithm will be run on. By default, this bit is set to 1, which means the memory mask that is downloaded from the ROM will overwrite the RAM info registers. The override bit can be reset by writing a 0 to it. In this case, the application can select the RAM groups to be tested by configuring the RAM info registers.

NOTE: When this override bit = 0, each algorithm selected in ALGO register will run on each RAM selected in RINFOL and RINFOU register. It must be ensured that:

1. Only the same type of memories (single port or two port) are selected, and
2. Only memories that are valid for all algorithms enabled via the ALGO register are selected.

If the above two requirements are not met, the memory self-test will fail.

Copyright © 2018, Texas Instruments Incorporated

9.5.6 Fail Status Fail Register (FSRF0)

This register indicates if a failure occurred during a memory self-test. Bit [0] gets set whenever a failure occurs. Figure 9-8 and Table 9-7 illustrate the FSRF0 register.

Figure 9-8. Fail Status Fail Register 0 (FSRF0) [offset = 0190h]

31	16

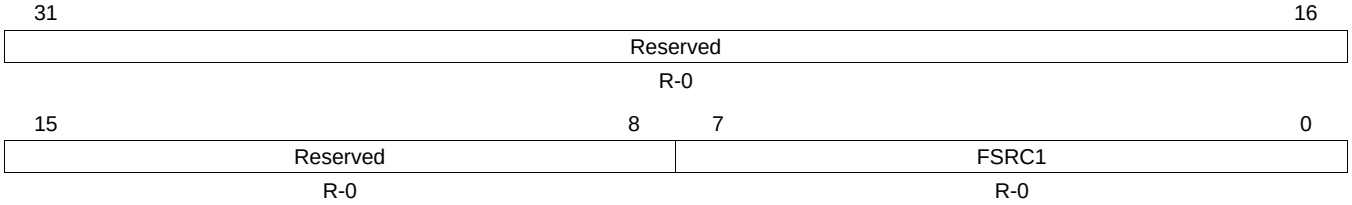
Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	FSRF0		Fail Status 0. This bit would be cleared by reset of the module using MSTGCR register in system module.
		0	No failure occurred.
		1	Failure occurred on port 0.

Copyright © 2018, Texas Instruments Incorporated

9.5.7 Fail Status Count Registers (FSRC0 and FSRC1)

These registers keep count of the number of failures observed during the memory self-test. The PBIST controller stops executing the memory self-test whenever a failure occurs in any memory instance for any of the test algorithms. The value in FSRC0 / FSRC1 gets incremented by one whenever a failure occurs and gets decremented by one when the failure is processed. FSRC0 is for Port 0 and FSRC1 is for Port 1. Figure 9-9 and Table 9-8 illustrate the FSRC0 register, while Figure 9-10 and Table 9-9 illustrate the FSRC1 register.

Figure 9-9. Fail Status Count 0 Register (FSRC0) [offset = 0198h]



LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 9-8. Fail Status Count 0 Register (FSRC0) Field Descriptions

Bit	Field	Value	Description
31-8	Reserved	0	Reads return 0. Writes have no effect.

9.5.9 Fail Status Data Registers (FSRDL0 and FSRDL1)

These registers are used to capture the failure data in case of a memory self-test failure. FSRDL0 corresponds to Port 0, while FSRDL1 corresponds to Port 1. Figure 9-13 and Table 9-12 illustrate the FSRDL0 register, while Figure 9-14 and Table 9-13 illustrate the FSRDL1 register.

9.5.10 ROM Mask Register (ROM)

This two-bit register sets appropriate ROM access modes for the PBIST controller. The default value is 11b. This register is illustrated in Figure 9-15. It can be programmed according to Table 9-14.

		0	No information is used from ROM.
		1h	Only RAM Group information from ROM.
		2h	Only Algorithm information from ROM.
		3h	Both Algorithm and RAM Group information from ROM. This option should be selected for application self-test.

Copyright © 2018, Texas Instruments Incorporated

9.5.11 ROM Algorithm Mask Register (ALGO)

This register is used to indicate the algorithm(s) to be used for the memory self-test routine. Each bit corresponds to a specific algorithm. For example, bit [0] controls whether algorithm 1 is enabled or not. Figure 9-16 and Table 9-15 illustrate this register.

NOTE: Please refer to Table 2-6 for available algorithms and the memories on which each algorithm can be run.

Copyright © 2018, Texas Instruments Incorporated

9.5.12 RAM Info Mask Lower Register (RINFOL)

This register is used to select the RAM groups 1 to 32 to run the algorithms selected in the ALGO register. For an algorithm to be executed on a particular RAM group, the corresponding bit in this register must be set to 1. The default value of this register is all 1s, which means all the RAM Groups are selected. Figure 9-17 and Table 9-16 illustrate this register.

The information from this register is used only when bit 0 in OVER register is not set.

9.5.13 RAM Info Mask Upper Register (RINFOU)

This register is used to select the RAM groups 33 to 64 to run the algorithms selected in the ALGO register. For an algorithm to be executed on a particular RAM group, the corresponding bit in this register should be set to 1. The default value of this register is all 1s, which means all the RAM Info Groups would be selected. Figure 9-18 and Table 9-17 illustrate this register.

9.6 PBIST Configuration Example

The following examples assume that the PLL is locked and selected as clock source with GCLK1 = 300 MHz and VCLK = 75 MHz.

9.6.1 Example 1 : Configuration of PBIST Controller to Run Self-Test on DCAN1 RAM

This example explains the configurations for running March13 algorithm on DCAN1.

1. Program the GCLK1 to PBIST ROM clock ratio to 1:4 in System Module.
   MSTGCR[9:8] = 2
2. Enable PBIST Controller in System Module.
   MSIENA[31:0] = 0x00000001
3. Enable the PBIST self-test in System Module.
   MSTGCR[3:0] = 0xA
4. Wait for at least 64 VCLK cycles in a software loop.
5. Enable the PBIST internal clocks.
   PACT = 0x1
6. Disable RAM Override. This will make the PBIST controller use the information provided by the application in the RINFOx and ALGO registers for the memory self-test.
   OVER = 0x0
7. Select the Algorithm (refer to Table 2-6).
   ALGO = 0x00000004 (Algo 3 = March13N for two-port DCAN1 RAM)
8. Program the RAM group Info to select DCAN1 (DCAN1 RAM is Group 3, refer to Table 2-5).
   RINFOL = 0x00000004 (select RAM Group 3)
   RINFOU = 0x00000000 (since we are testing only DCAN1)
9. Select both Algorithm and RAM information from on-chip PBIST ROM.
   ROM = 0x3
10. Configure PBIST to run in ROM Mode and start PBIST run.
    DLR = 0x14
11. Wait for PBIST test to complete by polling MSTDONE bit in System Module.
    while (MSTDONE !=1)
12. Once self-test is completed, check the Fail Status register FSRF0.
    In case there is a failure (FSRF0 = 1):
    a. Read RAMT register that indicates the RGS and RDS values of the failure RAM.
    b. Read FSRC0 and FSRC1 registers that contain the failure count.
    c. Read FSRA0 and FSRA1 registers that contain the address of first failure.
    d. Read FSRDL0 and FSRDL1 registers that contain the failure data.
    e. Resume the Test if required using Program Control register (offset = 0x16C) STR = 2.

    In case there is no failure (FSRF0 = 0), the memory self-test is completed.
    a. Disable the PBIST internal clocks.
       PACT = 0
    b. Disable the PBIST self-test.
       MSTGCR[3:0] = 0x5

Copyright © 2018, Texas Instruments Incorporated

9.6.2 Example 2 : Configuration of PBIST Controller to Run Self-Test on ALL RAM Groups

This example explains the configurations for running March13 algorithm on all RAM groups defined in the PBIST ROM.

1. Program the GCLK1 to PBIST ROM clock ratio to 1:4 in System Module.
   MSTGCR[9:8] = 2
2. Enable PBIST Controller in System Module.
   MSIENA[31:0] = 0x00000001
3. Enable the PBIST self-test in System Module.
   MSTGCR[3:0] = 0xA
4. Wait for at least 64 VCLK cycles in a software loop.
5. Enable the PBIST internal clocks.
   PACT = 0x1
6. Enable RAM Override.
   OVER = 0x1
7. Select the Algorithms to be run (refer to Table 2-6).
   ALGO = 0x0000000C (select March13N for single-port and two-port RAMs)
8. Select both Algorithm and RAM information from on-chip PBIST ROM.
   ROM = 0x3
9. Configure PBIST to run in ROM Mode and kickoff PBIST test.
   DLR = 0x14
10. Wait for PBIST test to complete by polling MSTDONE bit in System Module.
    while (MSTDONE !=1)
11. Once self-test is completed, check the Fail Status register FSRF0.
    In case there is a failure (FSRF0 = 1):
    a. Read RAMT register that indicates the RGS and RDS values of the failure RAM.
    b. Read FSRC0 and FSRC1 registers that contain the failure count.
    c. Read FSRA0 and FSRA1 registers that contain the address of first failure.
    d. Read FSRDL0 and FSRDL1 registers that contain the failure data.
    e. Resume the Test if required using Program Control register (offset = 0x16C) STR = 2.

    In case there is no failure (FSRF0 = 0), the Memory self-test is completed.
    a. Disable the PBIST internal clocks.
       PACT = 0
    b. Disable the PBIST self-test.
       MSTGCR[3:0] = 0x5

10.1 General Description

The self-test controller (STC) module is used to test the ARM CPU core and other complex digital IPs using the 'Deterministic Logic Built-in Self-Test' (LBIST) controller as the test engine. To achieve better coverage for the self-test of complex cores like Cortex-R5F, on-chip logic BIST is the preferred solution over software based self-test.

There are two STC modules implemented on this device. STC1 for redundant CPUs and their µSCU block. STC2 for the two nHET modules. The STC module provides the capability to test redundant IPs in parallel or individually.

10.1.1 Self-Test Controller Features

The self-test controller has the following features:

- Capable of running the complete test as well as running a single or multiple test sets (intervals) at a time.
  - Ability to continue from the last executed interval as well as the ability to restart from the beginning (first interval).
- Support of two logical segments. Figure 10-1 shows the implementation with multiple segments. Each interval can be mapped to a logical segment. A segment identifier corresponding to each interval is stored in the self-test ROM.
  - Segment 0: Segment 0 has the additional capability to test redundant logic or cores in one of the following modes:
    - Parallel Mode: Redundant logic cores are tested in parallel with the same patterns but have a dedicated signature generator. This is used in the safety critical redundant logic that runs in lock-step. Figure 10-2 and Figure 10-3 show this configuration for STC1 and STC2.
    - Split Mode: Each redundant logic is tested individually. Figure 10-4 and Figure 10-5 show this configuration for STC1.
  - All redundant cores (or IPs) within a segment have their own dedicated DBIST controllers.
  - Other segment (segment 1) can test only a single logic segment during the self-test run.
  - Ability to select segment for which the first interval is selected for run.
- Complete isolation of the self-tested core from the rest of the system during the self-test run
  - The self-tested CPU core master bus transaction signals are configured to be in idle mode during the self-test run
  - Any master access to the CPU core under self-test (example: DMA access to CPU TCM) will be held until the completion of the self-test
- Ability to capture the failure segment and interval number
- Timeout counter for the self-test run as a fail-safe feature
- Able to read the MISR data (shifted from LBIST controller) of the last executed interval of the self-test run for debugging purposes
- STCCLK determines the self-test execution speed, STC clock divider (STCCLKDIV) register is used to divide one of the system clocks to generate STCCLK. The divider can be configured per segment. For STC1, GCLK1 is divided down; for STC2, VCLK2 is divided down to generate STCCLK.
- Low-frequency shift. Programmable clock divider register inside STC to reduce the shift frequency in order to reduce the shift power.

Copyright © 2018, Texas Instruments Incorporated

10.1.2 Terminology

Interval: An interval corresponds to a test set that is the basic test unit for the STC module

Segment: A self-test segment corresponds to a portion of the unique/discrete safety critical logic which can be tested in isolation from the rest of the system by the self-test controller and DBIST logic. A self-test segment may correspond to a logic like CPU core (for example, Cortex-R5F) or an IP (for example, µSCU or nHET) or a sub-system.

The assignment of segments to digital logic is device dependent.

NOTE: All segments need to run sequentially during the self-test run. It is not recommended to switch from one segment to another before the self-test for the current segment is completed. The segment intervals in the STC ROM are organized sequentially.

10.1.3 STC Block Diagram

STC module provides an interface to the LBIST controller implemented on the CPUs and the nHET modules. There are two separate STC modules implemented: one for redundant Cortex-R5F CPUs and µSCU and another one for the nHET modules. Each STC module comprises of the same basic blocks and has same features and functionality.

The STC module is composed of following blocks of logic:

- ROM Interface
- FSM and Sequence Control
- Register Block
- Peripheral Bus Interface (VBUSP Interface)

10.1.3.1 ROM Interface

This block handles the ROM address and control signal generation to read the self-test microcode from the ROM. The test microcode and golden signature value for each interval are stored in ROM.

10.1.3.1.1 FSM and Sequence Control

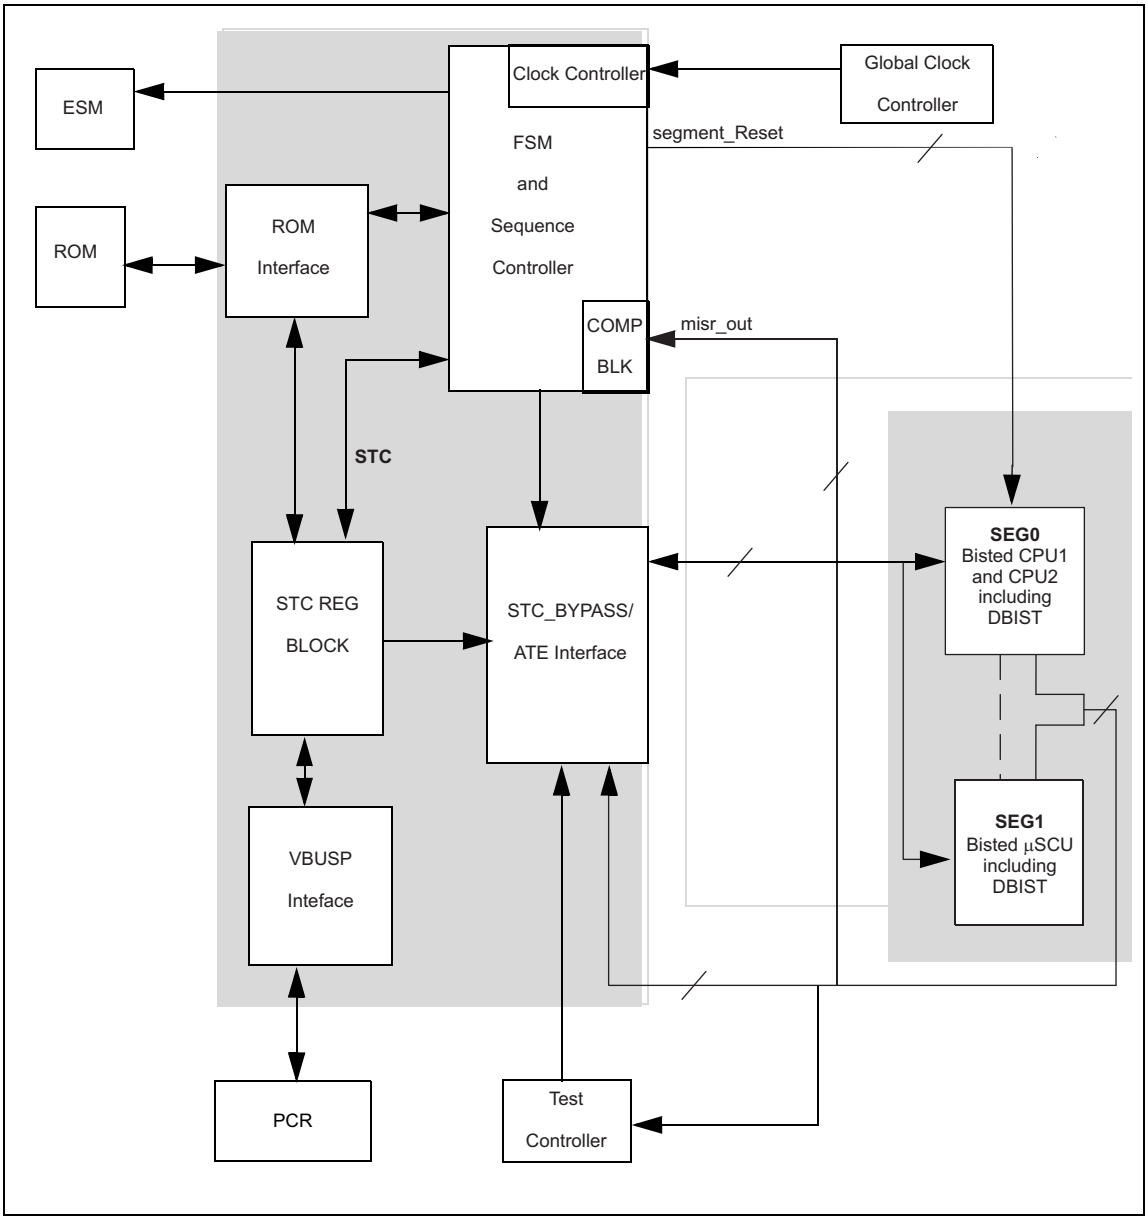
This block generates control signal and data to the LBIST controller based on the seed, test_type and scan chain depth.

10.1.3.1.2 Clock Control

The clock controller sub-block handles the internal clock selection and generation for the ROM, LBIST controller and logic under test.

The clock control ratio can be programmed in STC module by programming STCCLKDIV register.

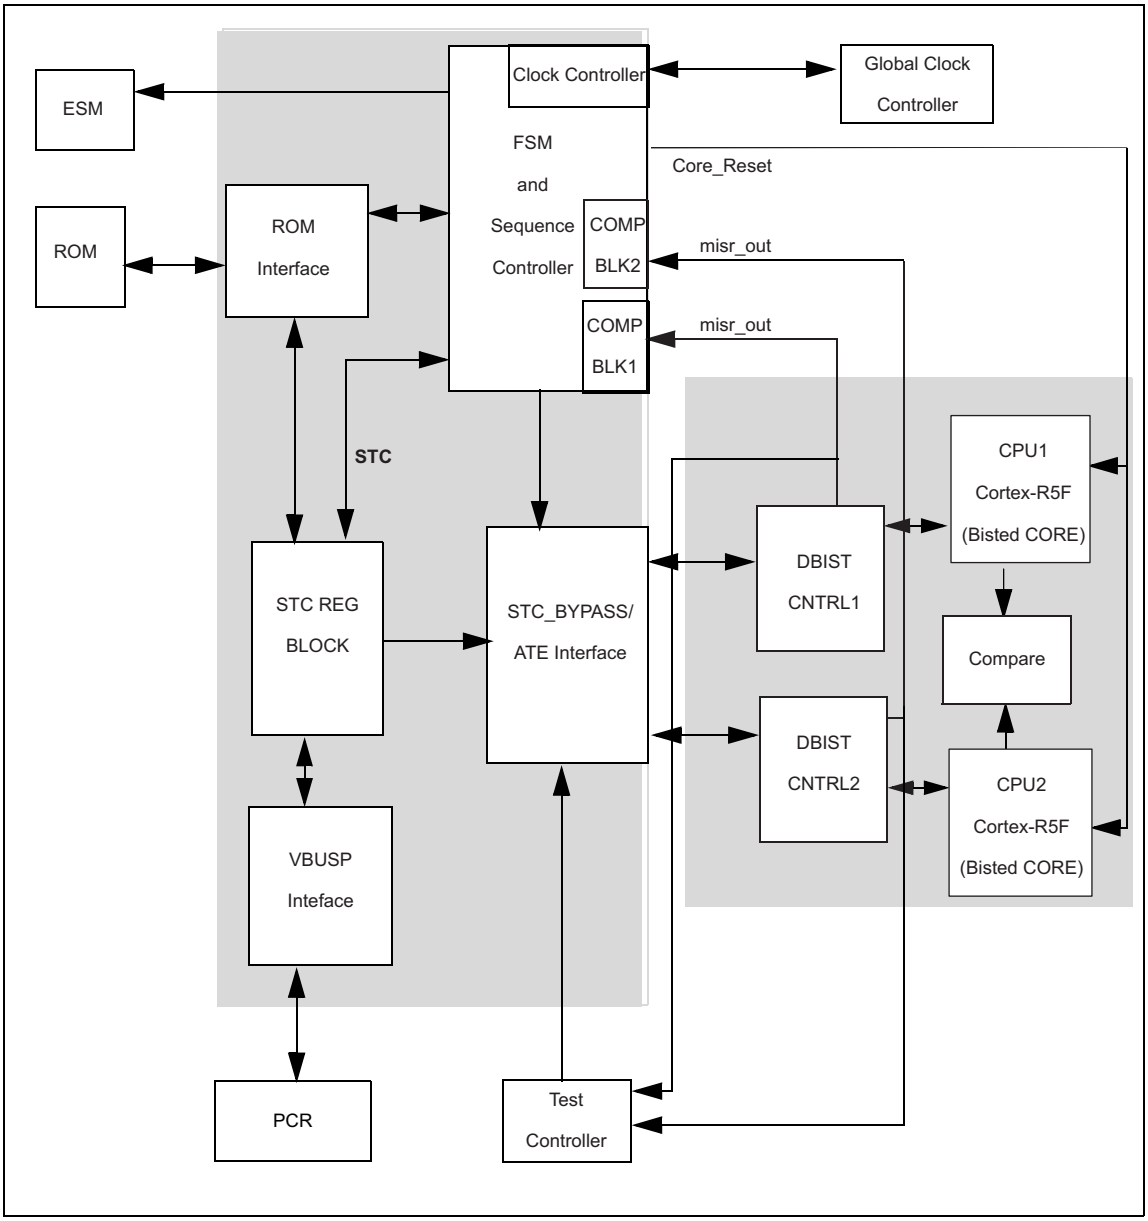
10.1.3.2 Register Block



This block handles the control of the self-test controller. This block contains various configuration and status registers that provide the result of a self-test run. These registers are memory mapped and accessible through the Peripheral Bus (VBUSP) Interface. This block controls the reseeding (reloading the existing seed of the PRPG) in the LBIST controller.

Copyright © 2018, Texas Instruments Incorporated

10.1.3.3 Peripheral Bus (VBUSP) Interface



STC control registers are accessed through Peripheral Bus (VBUSP) Interface. During application programming, configuration registers are programmed through the Peripheral Bus Interface to enable and run the self-test controller.

10.2 STC Module Assignments

There are two instances of STC modules available on this device, see Table 10-1. STC1 is used for running self-test on the redundant CPUs and µSCU. STC2 is used for running self-test on the two nHET modules. The two instances are independent of each other.

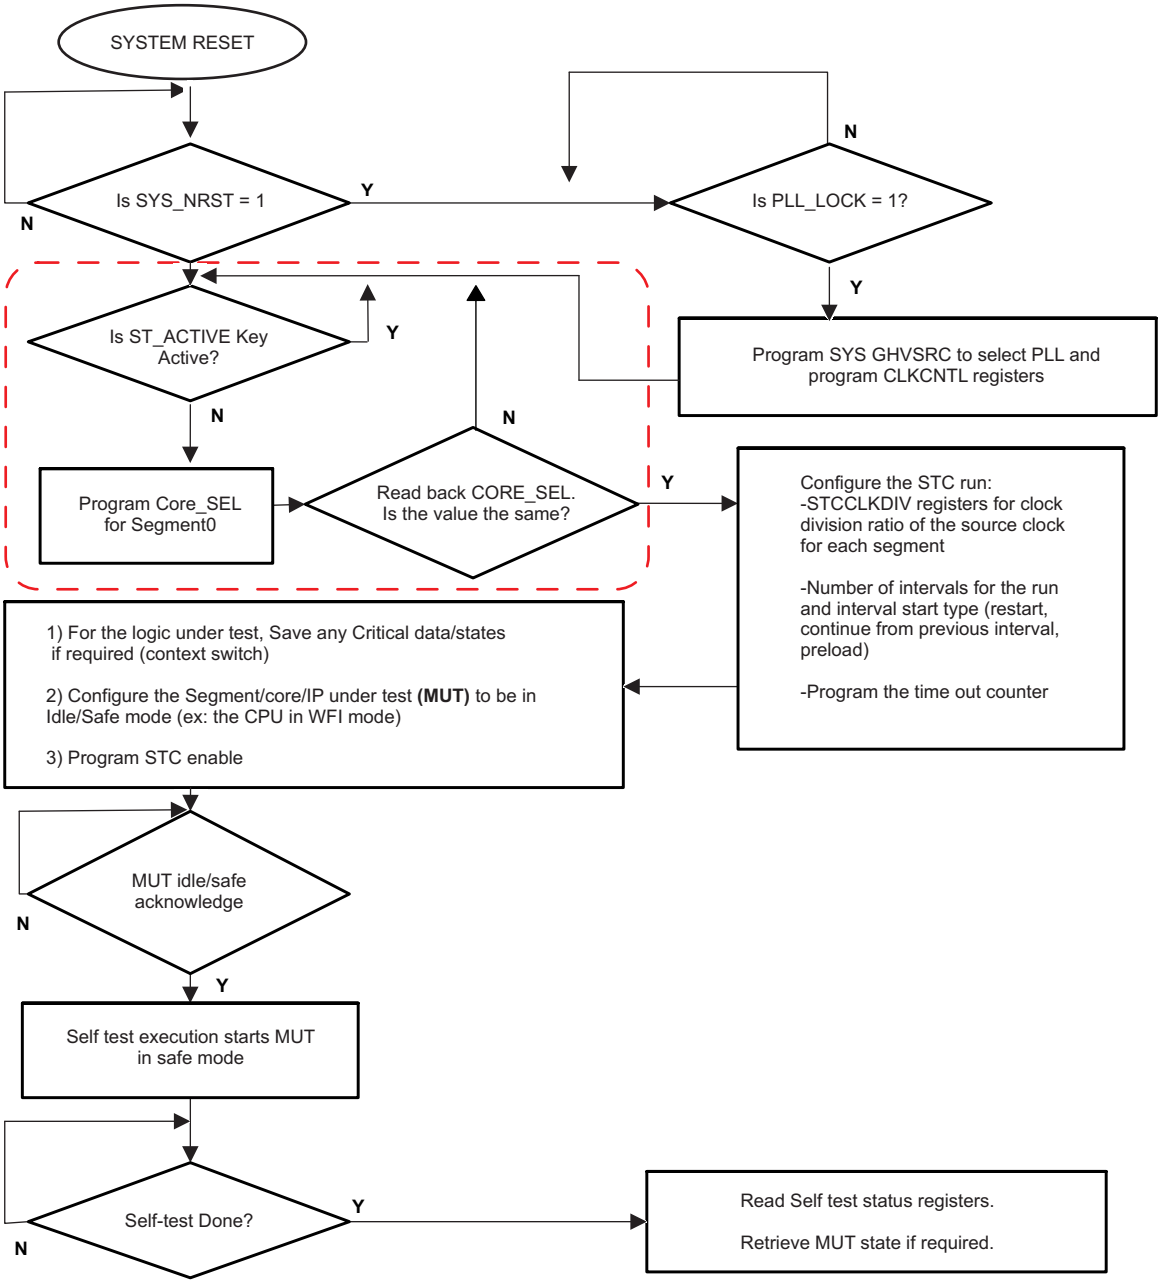

Table 10-1. STC Module Assignments

Module	Segments	Targeted IP	Number of Intervals	STCCLK Derived From	Note
STC1	Segment 0	CPU1 and CPU2	125	GCLK1	Segment 0 allows CPU1 and CPU2 to be tested in parallel or individually.
	Segment 1	µSCU (ACP Block)	3	GCLK1	None
STC2	Segment 0	nHET1 and nHET2	57	VCLK2	Segment 0 allows nHET1 and nHET2 to be tested in parallel or individually.

10.3 STC Programmers Flow

Figure 10-6. STC Programmers Flow Chart

The steps shown in red can be bypassed for self-test with single core only.

Copyright © 2018, Texas Instruments Incorporated

10.4 Application Self-Test Flow

This section describes the STC module configuration and the application self-test flow that you should follow for successful execution. The following two configurations must be part of the STC initialization code:

- STC clock rate configuration, STC clock divider (STCCLKDIV) register is used to divide system clock to generate STCCLK for each segment.
- Clear SYSESR register before triggering an STC test.

10.4.1 STC Module Configuration

- Configure the test interval count using STCGCR0[31:16] register. STC1, segment 0 supports a maximum of 125 intervals, STC1 segment 1 supports a maximum of 3 and STC2 supports a maximum of 57 intervals. The intervals within each group can be ran individually or sequentially at one time. If the test intervals are run individually, the user software can specify to the self-test controller whether to continue the run from the next interval or to restart from interval 0 using bit STCGCR0[0]. This bit gets reset after the completion of the self-test run.
- Configure self-test run timeout counter preload register STCTPR. This register contains the total number of VBUS clock cycles it will take before a self-test timeout error (TO_ERR) will be triggered after the initiation of the self-test run.
- Configure Segment 0 for parallel or serial execution for each of the 2 elements to be tested (primary and redundant logic).
- Enable self-test by writing the enable key to STCGCR1 register.

10.4.2 Context Saving - CPU

STC generates a CPU reset after completion of each test regardless of pass or fail. You can run the STC test during startup or can divide STC into subsets of 1 or more intervals and executed during application run time.

The STC test is a destructive test such that content within the element being tested may need to be preserved.

If STC is run only on startup, the user software need not save the CPU contents since the reset at the completion of the test will be followed by normal device initializations/startup configuration. During startup, the user code should check the STCGSTAT register for the self-test status before going to the application software.

If STC is divided into intervals and ran during application run time, the user software must save the CPU contents and reload them after each CPU reset caused by the completion of the STC test interval. The check for STC status should bypass the STC run if the reset is caused by a completed test execution. The STCGSTAT register should be checked for the self-test status before returning to the application software.

Following are some of the registers that are required to be backed up before and restored after self-test:

1. CPU core registers: all modes R0-R15, PC, CPSR
2. CP15 System Control Coprocessor registers: MPU control and configuration registers, Auxiliary Control Register used to Enable ECC, Fault Status Register
3. CP13 Coprocessor Registers: FPU configuration registers, General Purpose Registers
4. Hardware Break Point and watch point registers: BVR, BSR, WVR, WSR

For more information on the CPU reset, refer to the ARM® Cortex®-R5F Technical Reference Manual.

NOTE: Check all reset source flags in the SYSESR register after a CPU BIST execution. If a flag in addition to CPU reset is set, clear the CPU reset flag and service the other reset sources accordingly.

Copyright © 2018, Texas Instruments Incorporated

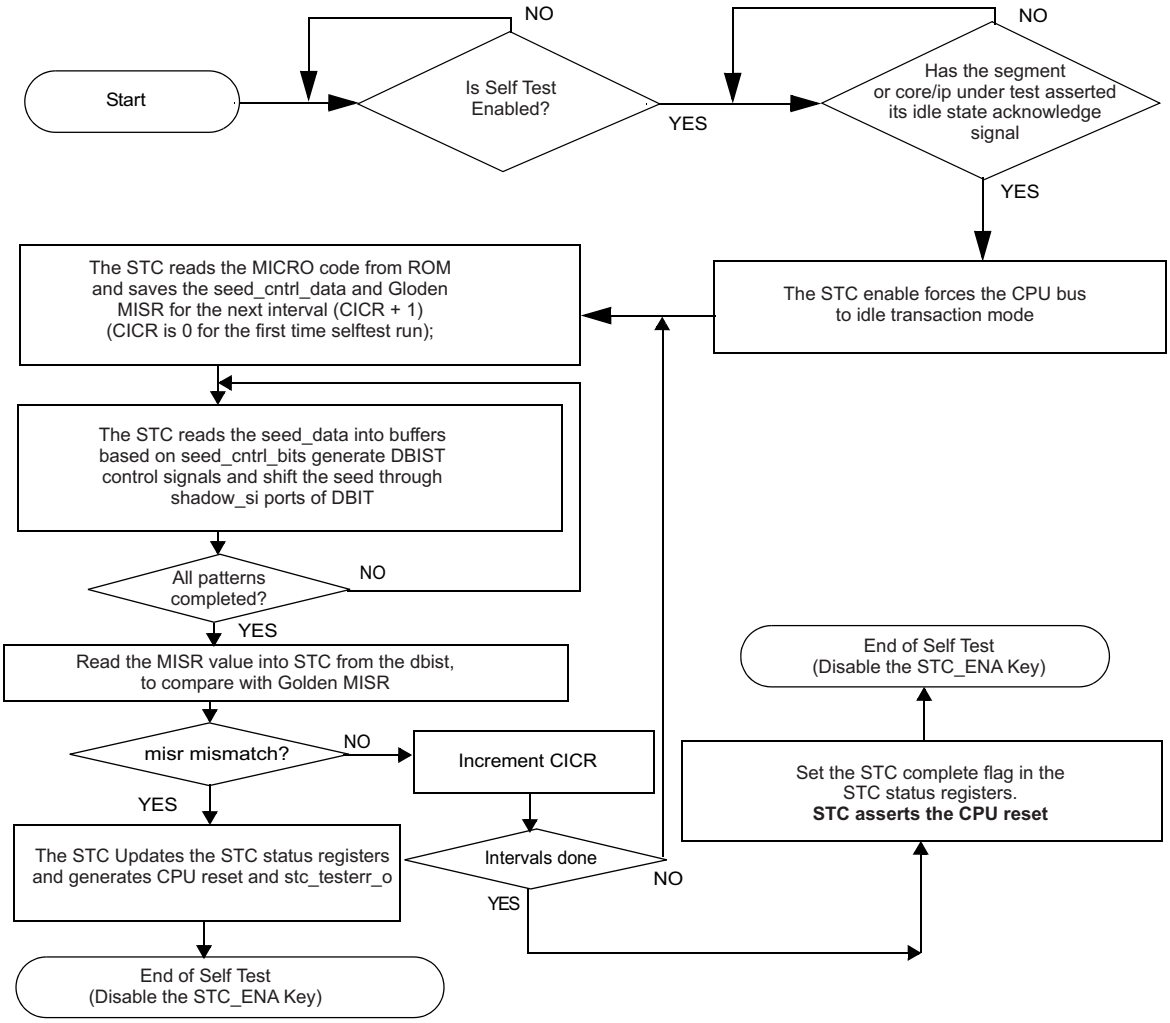
10.4.3 Entering CPU Idle Mode

After enabling the STC test by writing the STC enable key, the test is triggered only after the CPU is taken to idle mode by executing the CPU Idle Instruction **asm(“ WFI”).**

10.4.4 Entering nHET Idle Mode

After enabling the STC test by writing the STC enable key, the test is triggered only after the nHET module is put in reset state by writing to bit 0 the HETGCR Global Configuration Register in the nHET module.

10.4.5 Self-Test Completion and Error Generation



At the end of each interval, the 128 bit MISR value (reflected in registers CPUx_CURMISR[3:0]) from the DBIST controller is shifted into the STC. This is compared with the golden MISR value stored in the ROM.

At the end of a CPU self-test, the STC controller updates the status flags in the Global Status Register (STCGSTAT) and resets the CPU. In case of a MISR mismatch or a test timeout, an error is generated through the ESM module. TEST_ERR signal is asserted when an MISR miscompare occurs during the self-test. A TO_ERR is asserted when a timeout occurs during the self-test, meaning the test could not complete within the time specified in the timeout counter preload register STCTPR. However, at the device level, these two errors are combined and mapped to a single ESM channel. To identify which error occurred, user software must check the global status register (STCGSTAT) and fail status register STCFSTAT in the ESM interrupt service routine.

Figure 10-7 illustrates the self-test hardware execution flow chart, based on the assumption that the device has gone through startup, necessary clocks initialized and SYSESR register bits cleared.

10.8 STC Control Registers

STC control registers are accessed through Peripheral Bus (VBUSP) interface. Read and write access in 8,16, and 32 bit are supported.

The base address for the control registers of STC1 is FFFF E600h. The base address for the control registers of STC2 is FFFF 0800h.

NOTE: In suspend mode, all registers can be written irrespective of user or privilege mode and reads will not clear the 'read-clear' (RC) bits.

Table 10-8. STC Control Registers

Offset	Acronym	Register Description	Section
00h	STCGCR0	STC Global Control Register 0	Section 10.8.1

10.8.1 STC Global Control Register 0 (STCGCR0)

This register is described in Figure 10-8 and Table 10-9.

NOTE: On a power-on reset or system reset, this register gets reset to its default values.

Figure 10-8. STC Global Control Register 0 (STCGCR0) [offset = 00h]

31	16
INTCOUNT	
R/WP-1	

15	11	10	8	7	2	1	0
Reserved		CAP_IDLE_CYCLE		Reserved		RS_CNT	
R-0		R/WP-1		R-0		R/WP-0	

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privilege mode only; -*n* = value after reset

Table 10-9. STC Global Control Register 0 (STCGCR0) Field Descriptions

Bit	Field	Value	Description
31-16	INTCOUNT		Number of intervals of self-test run.
		0-FFFFh	This register specifies the number of intervals to run for the self-test run. This corresponds to the number of intervals to be run from the value reflected in the current interval counter.
15-11	Reserved	0	Reads return 0. Writes have no effect.
10-8	CAP_IDLE_CYCLE		Idle cycle before and after the capture clock.
		0	Disabled
		1	Enabled
7-2	Reserved	0	Reads return 0. Writes have no effect.
1-0	RS_CNT		Restart or Continue
			This bit specifies whether to continue the run from next interval onwards or to restart from interval 0. This bit gets reset after the completion of a self-test run.
		0	Continue STC run from the previous interval.
		1h	Restart STC run from interval 0.
		2h-3h	Reserved

Copyright © 2018, Texas Instruments Incorporated

10.8.2 STC Global Control Register 1 (STCGCR1)

This register is described in Figure 10-9 and Table 10-10.

NOTE: On a power-on reset or system reset, this register resets to its default values. Also, this register automatically resets to its default values at the completion of a self-test run.

The SEG0_CORE_SEL bits must be written first before the STC_ENA bits are written, in order for the STC to properly initiate the selected core for self-test.

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privilege mode only; -*n* = value after nPORST (power on reset) or System reset

Table 10-10. STC Global Control Register 1 (STCGCR1) Field Descriptions

Bit	Field	Value	Description
31-12	Reserved	0	Reads return 0. Writes have no effect.
11-8	SEG0_CORE_SEL		Selects cores in Segment 0 for self-test. These bits can be programmed only when SEG0_CORE_SEL is 0000. Once the field is written it ignores all further writes until the self-test sequence completes. This is to maintain coherency for self-test runs.
		5h	Select only Core1 for self-test.
		Ah	Select only Core2 for self-test.
		All other values	Select both cores for self-test in parallel.
7-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	STC_ENA		Self-test run enable key.
		Ah	Self-test run is enabled.
		All other values	Self-test run is disabled.

10.8.3 Self-Test Run Timeout Counter Preload Register (STCTPR)

This register is described in Figure 10-10 and Table 10-11.

NOTE: On a power-on reset or system reset, this register gets reset to its default values.

Figure 10-10. Self-Test Run Timeout Counter Preload Register (STCTPR) [offset = 08h]

31	0
RTOD	
R/WP-FFFF FFFFh	

LEGEND: R/W = Read/Write; WP = Write in privilege mode only; -*n* = value after nPORST (power on reset) or System reset

Table 10-11. Self-Test Run Timeout Counter Preload Register (STCTPR)

Bit	Field	Description
31-0	RTOD	Self-test timeout count preload. This register contains the total number of VBUS clock cycles it will take before an self-test timeout error (TO_ERR) will be triggered after the initiation of the self-test run. This is a fail safe feature to prevent the device from hanging up due to a run away test during the self-test. The preload count value gets loaded into the self-test time out down counter whenever a self-test run is initiated (STC_KEY is enabled) and gets disabled on completion of a self-test run.

Copyright © 2018, Texas Instruments Incorporated

10.8.4 STC Current ROM Address Register - CORE1 (STCCADDR1)

This register is described in Figure 10-11 and Table 10-12.

NOTE: When the RS_CNT bit in STCGCR0 is set to a 1 on the start of a self-test run, or on a power-on reset or system reset, this register resets to all zeroes.

Figure 10-11. STC Current ROM Address Register (STCCADDR1) [offset = 0Ch]

ADDR	
R-0	

LEGEND: R = Read only; -*n* = value after nPORST (power on reset) or System reset

Table 10-12. STC Current ROM Address Register (STCCADDR1) Field Descriptions

Bit	Field	Description
31-0	ADDR	Current ROM Address This register reflects the current ROM address (address or micro code load) accessed during self-test Segment0 -Core1 and other segments. This is the current value of the STC program counter.

10.8.5 STC Current Interval Count Register (STCCICR)

This register is described in Figure 10-12 and Table 10-13.

NOTE: When the RS_CNT bit in STCGCR0 is set to a 1 or on a power-on reset, the current interval counter resets to the default value.

Figure 10-12. STC Current Interval Count Register (STCCICR) [offset = 10h]

Table 10-13. STC Current Interval Count Register (STCCICR) Field Descriptions

Bit	Field	Description
31-16	CORE2_ICOUNT	Interval Number This specifies the last executed interval number for Core2 in case of self-test being run on Segement0 redundant cores.
15-0	CORE1_ICOUNT	Interval Number This specifies the last executed interval number for Core1 in case of self-test being run on Segment0 or any other segments.

Copyright © 2018, Texas Instruments Incorporated

10.8.6 Self-Test Global Status Register (STCGSTAT)

This register is described in Figure 10-13 and Table 10-14.

NOTE: The two status bits can be cleared to their default values on a write of 1 to the bits. Additionally when the STC_ENA key in STCGCR1 is written from a disabled state to an enabled state, the two status flags get cleared to their default values. This register gets reset to its default value with power-on reset assertion.

R-0		R-5h		R-0		R/W1CP-0	R/W1CP-0

LEGEND: R/W = Read/Write; R = Read only; W1CP = Write 1 to clear in privilege mode; -*n* = value after reset

Table 10-14. Self-Test Global Status Register (STCGSTAT) Field Descriptions

Bit	Field	Value	Description
31-12	Reserved	0	Reads return 0. Writes have no effect.
11-8	ST_ACTIVE		This field indicates if the self-test is active.
		Ah	Self-test is active.
		All other values	Self-test is not active.
			This will be set in the cycle after CORE_SEL is programmed. This will be reset once the STC generated the CPU reset after completion of the self-test.
7-2	Reserved	0	Reads return 0. Writes have no effect.
1	TEST_FAIL		Test Fail
		0	Self-test run has not failed.
		1	Self-test run has failed.
0	TEST_DONE		Test Done
		0	Self-test run is not completed.
		1	Self-test run is completed.
			The test done flag is set to a 1 for any of the following conditions: 1. When the STC run is complete without any failure 2. When a failure occurs on a STC run 3. When a timeout failure occurs Reset is generated to the CPU on which the STC run is being performed when TEST_DONE goes high (the test is completed).

Copyright © 2018, Texas Instruments Incorporated

10.8.7 Self-Test Fail Status Register (STCFSTAT)

This register is described in Figure 10-14 and Table 10-15.

NOTE: The three status bits can be cleared to their default values on a write of 1 to the bits. Additionally when the STC_ENA key in STCGCR1 is written from a disabled state to an enabled state, the three status bits get cleared to their default values. This register gets reset to its default value with power-on reset assertion.

When multiple segments are enabled in a self-test run, the STC will indicate the self-test complete on the first failed interval corresponding to a segment. The subsequent segments will not be run. FSEG_ID bits in this register indicate which segment failed.

10.8.10 Signature Compare Self-Check Register (STCSCSCR)

This register is described in Figure 10-23. This register is used to enable the self-check feature of the CPU Self-Test Controller's (STC) signature compare logic. Self-check can only be done for the STC interval 0 by setting the RS_CNT bit in STCGCR0 to 1 to restart the self-test. The STC run will fail for signature miss-compare, provided the signature compare logic is operating correctly. To proceed with regular CPU self-test, STCSCSCR should be programmed to disable the self-check feature and clear the RS_CNT bit in STCGCR0 to 0. This register gets reset to its default value with any system reset assertion.

Figure 10-23. Signature Compare Self-Check Register (STCSCSCR) [offset = 3Ch]

Table 10-18. Signature Compare Self-Check Regsiter (STCSCSCR) Field Descriptions

Bit	Field	Value	Description
31-5	Reserved	0	Reads return 0. Writes have no effect.
4	FAULT_INS		Enable fault insertion.
		0	No fault is inserted.
		1	Insert stuck-at-fault inside CPU so that STC signature compare will fail.
3-0	SELF_CHECK_KEY		Signature compare logic self-check enable key.
		Ah	Signature compare logic self-check is enabled. This allows a fault to be inserted using the FAULT_INS field.
		All other values	Signature compare logic self-check is disabled The FAULT_INS field has no effect in this case.

10.8.11 STC Current ROM Address Register - CORE2 (STCCADDR2)

This register is described in Figure 10-24 and Table 10-19.

NOTE: When the RS_CNT bit in STCGCR0 is set to a 1 on the start of a self-test run, or on a power-on reset or system reset, this register resets to all zeroes.

10.8.12 STC Clock Prescalar Register (STCCLKDIV)

This register is described in Figure 10-25. This register is used to configure STC clock divider ratio for each segment. STCCLK is derived from the system clock (GCLK1 for STC1 and VCLK2 for STC2) and the configured ratio is applied when the corresponding segment is under test. The division ratio programmed in this register will have effect only when the value in the CLKDIV field of the STCLKDIV register (FFFF E108h) from SYS2 module is zero. Else the division ratio will be taken from SYS2. This is done for software compatibility.

NOTE: The clock divider ratio is applied when the corresponding segment is under test.

10.8.13 Segment Interval Preload Register (STCSEGPLR)

This register is described in Figure 10-26. This register is used to specify the segment for which the first interval will be run. The address of the first interval of the selected segment is loaded to the STC ROM address counter before the test is started.

Figure 10-26. Segment Interval Preload Register (STCSEGPLR) [offset = 48h]

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privilege mode only; -*n* = value after nPORST (power on reset) or System reset

10.9 STC Configuration Example

The following example provides steps to configure STC1 to run self-test on CPUs and the µSCU unit. It that the PLL is locked and selected as the system clock source with GCLK1 = 330 MHz and HCLK = 110 MHz prior to going through the following configurations.

10.9.1 Example: STC1 Self-Test Run

This example explains the configurations for running STC Test for on 40 test intervals.

1. Maximum STC clock rate support at 330 MHz GCLK1 is 110 MHz. Divide GCLK1 by 3 to achieve this clock rate. Bits STCCLKDIV[26:24] and STCCLKDIV[18:16] need to be configured.
   STCCLKDIV[26:24] = 2, STCCLKDIV[18:16] = 2
2. Clear CPU RST status bit in the System Exception Status Register in the system module.
   SYSESR[5] = 1
3. Configure the test interval count in STC module. Note that in case of multiple segments, segments run sequentially, one after another depending on the number of intervals selected.
   STCGCR0[31:16] = 40.
4. Configure self-test run time out counter preload register.
   STCTPR[31:0] = 0xFFFFFFFF
5. Optionally, configure SEG0_CORE_SEL bits in register STCGCR1 to select one of the redundant cores. By default bits SEG0_CORE_SEL are clear, which configures the STC to run both redundant cores in parallel.
6. Enable CPU self-test.
   STCGCR1[3:0]= 0xA;
7. Perform a context save of CPU state and configuration registers that get reset on CPU reset.
8. Put the CPU in idle mode by executing the CPU idle instruction.
   asm(“ WFI”)
9. Upon CPU reset, verify the CPU RST status bit in the System Exception Status Register is set. This also verifies that no other resets occurred during the self-test.
   SYSESR[5] == 1
10. Check the STCGSTAT register for the self-test status.
    Check TEST_DONE bit before evaluating TEST_FAIL bit.
    If (TEST_DONE = 1 and TEST_FAIL = 1), the self-test is completed and Failed.
    - Read STC Fail Status Register STCFSTAT[2:0] to identify the type of Failure (Timeout, CORE1 fail, CORE2 fail, FSEG_ID).

    In case there is no failure (TEST_DONE = 1 and TEST_FAIL = 0), the CPU self-test is completed successfully.
    - Recover the CPU status, configuration registers and continue the application software.

Copyright © 2018, Texas Instruments Incorporated

10.10 Self-Test Controller Diagnostics

This section provides the recommended flow for the self-test controller diagnostics. This test is recommended to be done at the application startup only, not with individual interval runs during the application.

Step 1: Configure the interval count to 1 in STCGCR0 register.

Segment 0

Step 2: Enable the SELF_CHECK_KEY and FAULT_INS bits in the STCSCSCR register and kick off the self-test by enabling the first interval of segment 0. On the completion of self-test, TEST_FAIL bit will be set in the STCGSTAT register. Check if the FSEGID bits in the STCFSTAT register are set to 00. Depending on the segment 0 configuration (parallel or individual cores), the CORE1_FAIL or CORE2_FAIL bits would be set.

Step 3: Disable one or both of the SELF_CHECK_KEY and FAULT_INS bits in the STCSCSCR register. Then restart the self-test by programming bit 0 of the STCGCR0 register to 1. On the completion of the test, the TEST_FAIL bit will be cleared in the STCGSTAT register.

Segment 1 (for STC1 only)

Step 4: Configure the SEGID_PLOAD bits in STCSEGPLR register to select the first interval of segment 1. Configure RS_CNT bit in STCGCR0 register to 1. This will start the self-test from the first interval of the selected segment. On the completion of self-test, TEST_FAIL bit will be set in the STCGSTAT register. Check if the FSEGID bits in the STCFSTAT register are set to 01.

Step 5: Disable one or both of the SELF_CHECK_KEY and FAULT_INS bits in the STCSCSCR register. Then restart the self-test by programming bit 0 of the STCGCR register to 1. On the completion of the test, the TEST_FAIL bit will be cleared in the STCGSTAT register.

After the diagnostics, the application can continue with the self-test as described in Section 10.4.

System Memory Protection Unit (NMPU)

This chapter describes the System Memory Protection Unit (NMPU).

Topic **Page**

11.1 Overview **461**
11.2 Module Operation **463**
11.3 How to Use NMPU **466**
11.4 NMPU Registers **471**

Copyright © 2018, Texas Instruments Incorporated

11.1 Overview

The System Memory Protection Unit module(s) provide an mechanism to control the memory access rights of bus masters in the system other than the host CPU. The programmer's model for the System Memory Protection unit is similar to but a subset of the host CPU's own memory protection unit. It allows memory partition into multiple regions and allows individual access protection for each region from a bus master point of view. An access from bus master is checked against each memory region access permission to make sure that the access from bus master does not alter the unintended memory region that could cause a system failure.

11.1.1 Features

NMPU offers the following main features:

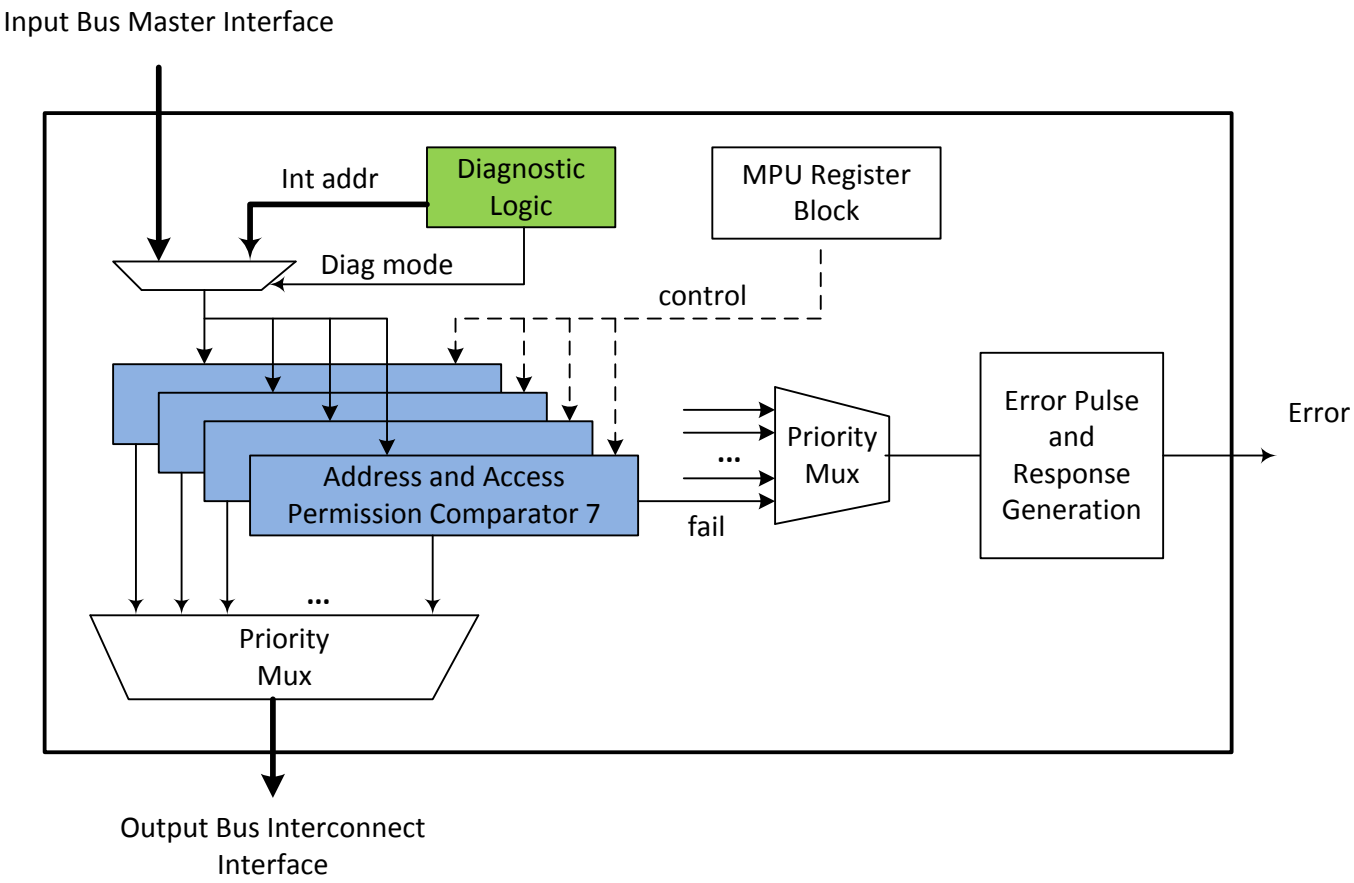
- Software programmer model is similar to but a subset of the host CPUs own memory protection unit.
- Provide protection to memory regions ranging from 32-bytes to 4GB in size
- Up to 8 memory protection regions. Note that the number of memory region is different for each bus master IP that the NMPU is dedicated for. Each region is defined by the base address and region size that are programmable in NMPU control registers. Table 11-1 defines the number of region available for the corresponding bus master IP.
- Programmable access permissions for each region such as full access, read-only, write-only, and no access.
- Different access permissions for user and privilege mode.
- On access violation, NMPU can notify ESM if ERRENA key in MPUCTRL1 register (Section 11.4.7) is enabled.

Table 11-1. NMPU Region

NMPU Module	Number of Available Regions
DMA-NMPU	8
Peripheral Interconnect Subsystem-NMPU	8
EMAC-NMPU	2

11.1.2 Safety Diagnostic

NMPU offers the following safety diagnostic capabilities:



- Provide a lock mechanism to avoid unintentional changes to NMPU control registers.
- Provide diagnostic capability to check the MPU region access permission logic.

Copyright © 2018, Texas Instruments Incorporated

11.1.3 Block Diagram

Figure 11-1 shows the block diagram of NMPU.

Figure 11-1. NMPU Block Diagram

Copyright © 2018, Texas Instruments Incorporated

11.2 Module Operation

11.2.1 Functional Mode

On reset, NMPU is disabled and no filtering will be done on the bus. User must ensure that no bus transaction from the master is on going while NMPU is getting disabled or enabled. This is similar to the need to flush transactions using memory barrier instructions on the CPU before changing CPU MPU setting.

The MPU can be enabled by writing 0xAh to the MPUENA key bits of MPUCTRL1 register and can be disabled by writing 0x5h to the same bits.

Access permission (AP) for each MPU region is defined in AP field in the MPU region access control register (MPUREGACR), see Table 11-2.

Table 11-2. Access Permission

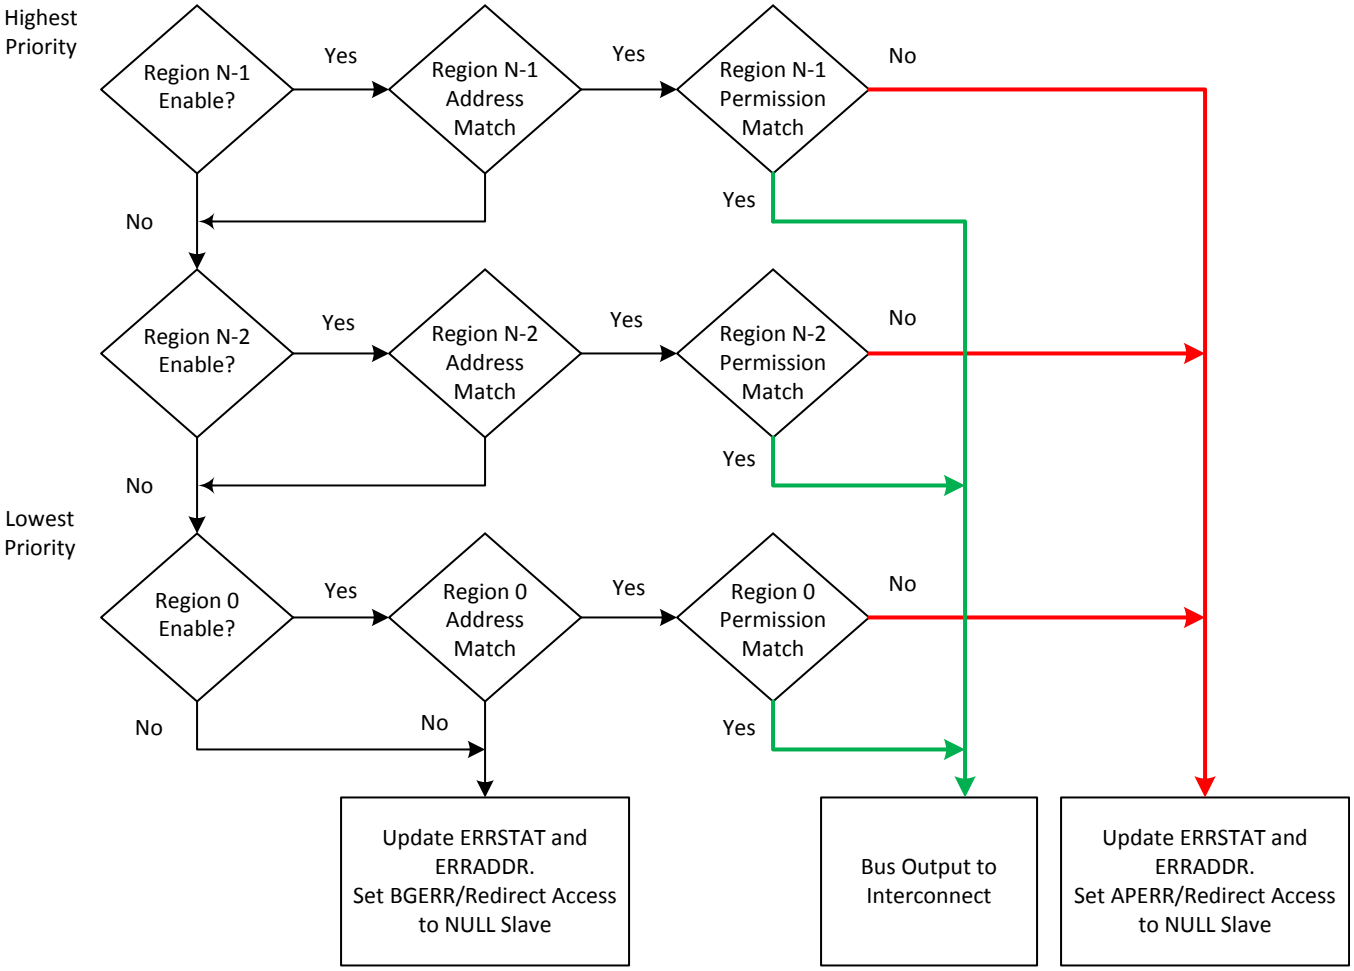
AP Field	Privilege Mode Permissions	User Mode Permissions
000	No Access	No Access
001	Read/Write	No Access
010	Read/Write	Read Only
011	Read/Write	Read/Write
100	No Access	No Access
101	Read only	No Access
110	Read only	Read only
111	No Access	No Access

Each MPU region has three control registers:

- MPUREGBASE: MPU based address register. It defines the base address for a particular MPU region
- MPUREGSENA: MPU region size and enable register. It defines the size of a particular MPU region and allows you to enable the region
- MPUREGACR: MPU region access control register. It defines the MPU region accessing permission for user or privilege mode

NMPU has one region register that you have to configure to determine which MPU region user is programming the corresponding MPUREGBASE, MPUREGSENA, and MPUREGACR registers. In this scheme, the MPUREGBASE, MPUREGSENA, and MPUREGACR can share the same memory map offset from user programming point of view.

Size of each MPU region can vary from 32 bytes to 4 GB. Region based address must start at an offset that is a multiple of region size. In case the base address does not start at an offset that is a multiple of region size, the region size takes priority and MPU ignores the LSB bits of base address.



Overlapping regions enable efficient programming of memory map. When the incoming address hits multiple MPU regions, access permission is decided by the highest numbered region for which there was an address compare match. In MPU configuration with 8 regions, region 0 has the lowest priority and region 7 has the highest priority.

Figure 11-2 shows how the region priority is resolved in a high-level abstraction.

MPU does not support default background memory map. If memory protection is enabled without region configuration, all transactions will result in bus error response. Before the protection unit is enabled, care needs to be taken to ensure that at least one valid protection region is specified and its access permission fields are defined.

11.2.2 Diagnostic Mode

Diagnostic mode can be used to verify the MPU address and access permission comparator logic. Entering or exiting the diagnostic mode will automatically clear the MPUERRSTAT and MPUERRADDR registers. Memory protection must be disabled while entering or exiting diagnostic mode. There are two different diagnostic modes: internal diagnostic mode and external diagnostic mode.

11.2.2.1 Internal Diagnostic Mode

In internal diagnostic mode, diagnostic logic inside the NMPU module drives the input of the MPU address and access permission comparator logic. You can program the address for which comparison needs to be performed and the type of transaction (read/write and user/privilege). For every write to the MPUDIAGADDR register, an address and access permission comparison is performed and the results are stored in MPUERRSTAT and MPUERRADDR registers. ERROR output to ESM will be generated if ERRENA key in MPUCTRL2 register is Ah. You must ensure that no bus transactions from the master are going on while NMPU is in internal diagnostic mode. NMPU does not accept any access originated from the bus master and ensures that the internal diagnostic logic will not result in any bus transactions on to the bus interconnect.

How to use the internal diagnostic mode is discussed in Section 11.3.

11.2.2.2 External Diagnostic Mode

In external diagnostic mode, the actual bus master initiates the access to the NMPU. Address of the access from the bus master is replaced by the address in MPUDIAGADDR register before the address reaches the address comparator logic. In this mode, both bus error response and ERROR pulse to ESM (if ERRENA = Ah) are generated for accesses that violate the access permissions. This diagnostic mode is useful to test the full signal chain from bus master access generation logic to NMPU comparator logic.

How to use the external diagnostic mode is discussed in Section 11.3.

11.2.3 Functional Fail Safe

Since NMPU module check and manipulate address or mode of bus master transaction, it is important to have functional fail safe features to guarantee that faults in MPU region checking, address translation, or user mode translation can be detected.

11.2.3.1 Run-time Diagnostics for Functional Features

Since features like input address masking, address translation and mode translation are integrated along with a critical function like memory protection, NMPU needs to have the following hardware logic for run-time diagnostics. This logic is implemented using 1oo1D safety architecture.

- There are two independent blocks (primary and checker) running in lock-step and compare address masking output every cycle. Outputs from NMPU are driven by the primary block.
- There are two independent blocks (primary and checker) running in lock-step and compare address translation output every cycle. Outputs from NMPU are driven by the primary block.
- There are two independent blocks (primary and checker) running in lock-step and compare mode translation output every cycle. Outputs from NMPU are driven by the primary block.
- If there is a lockstep comparison error, DIAGERR bit in MPUERRSTAT register is set to 1. ERRFLAG bit in the same register is also set. ERROR pulse output to ESM is generated irrespective of ERRENA key value in MPUCTRL2 register.
- A fault insertion allows user verifying that the individual lockstep comparator logic is functional and avoid latent fault. User can program the fault insertion bits in MPUDIAGCTRL register to introduce a fault in one of the lockstep comparator inputs for input address masking, address translation or mode translation during start up or shut down of the device.

Copyright © 2018, Texas Instruments Incorporated

11.2.3.2 Lock Feature for NMPU

Lock feature prevents unintentional updates to NMPU registers. Writes to registers other than MPUERRSTAT is possible only when NMPU is unlocked by writing 0xAh to LOCK key bits of MPULOCK register. On reset, these bits are set to 0x5h and hence the NMPU registers are in the locked state. All NMPU registers are writable only in privilege mode. There is no built in protection based on master ID. It is user responsibility to ensure that only a single valid privilege master updates the MPU registers.

11.2.3.3 Multibit Keys for Feature Enable/Disable

4-bit key is used to protect critical function enters enable or disable state from soft error. These key are updated only if the write data is 0x5h or 0xAh. Register write is ignored for all other write values. A built in correction logic detects single bit soft error on this field and corrects the value in the next cycle. Functionality and register read data remain the same during the correction cycle.

11.3 How to Use NMPU

11.3.1 How to Use NMPU in Functional Mode

The NMPU is used to configure the bus master MPU region in such a way that the bus master does not interfere with the memory region reserved for other tasks and not belonging to the system partitioning for the IP.

Once user determines the architectural memory partitioning of the IP bus masters on memory system frame according to their application, user should configure the corresponding MPU region for each bus master accordingly.

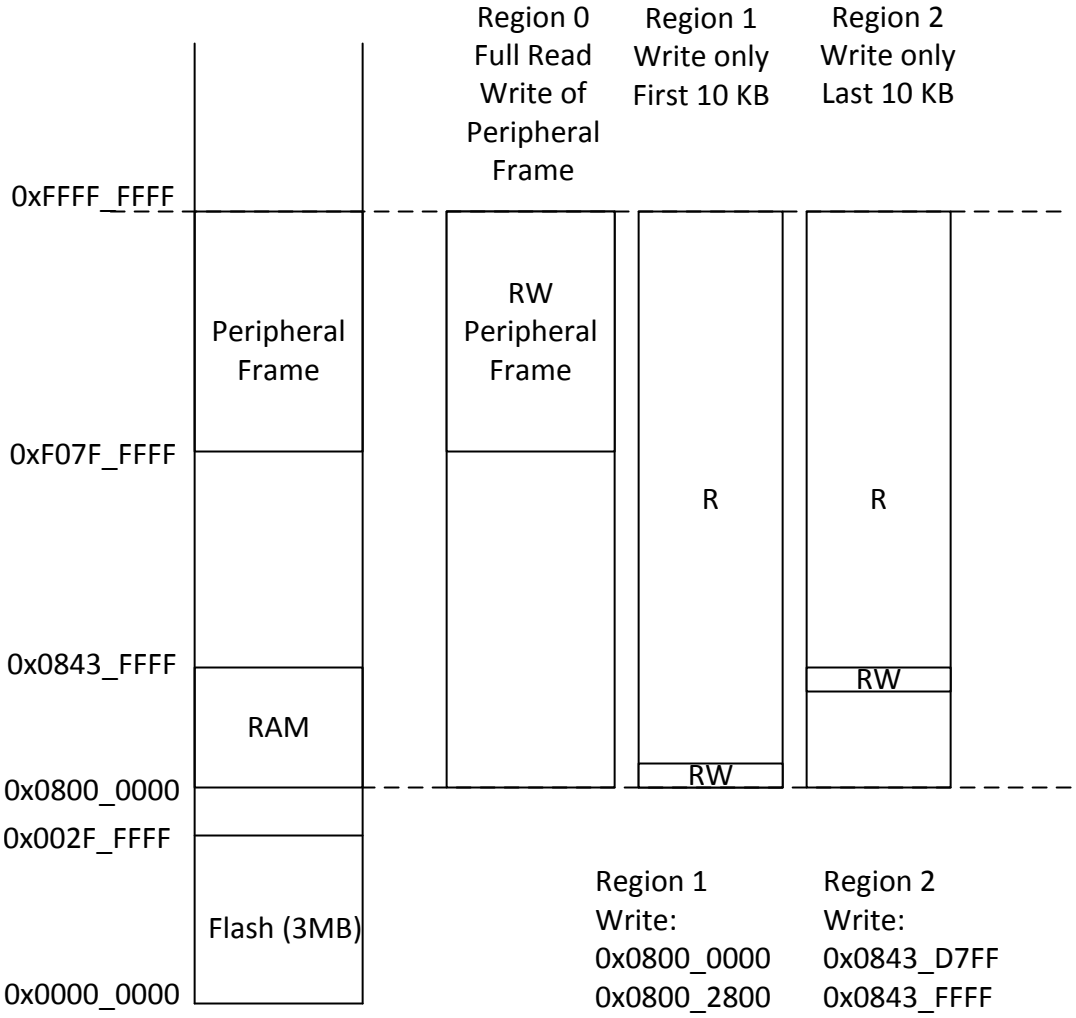
Figure 11-3 shows the example recommended memory setting for a bus master in the device, for example, DMA.

Assume the DMA bus master has 3 MPU regions.

The lowest priority MPU region1 is programmed to enable full read and write to peripheral memory frame.

MPU region 2 is programmed to allow read and write to a lower 10KB portion of the system RAM starting from 0x0800_0000.

MPU region 3 is programmed to allow read and write to the upper 10KB away from 0x0843_FFFF portion of the system RAM.



Any access in between 0x0800_2800 and 0x0843_D7FF is a read only mode for DMA.

With this configuration, DMA can have read or write access to the entire peripheral frame and only able to write to upper or lower 10KB of the system RAM.

The rest of the system RAM is reserved for other tasks in which the DMA should not interfere with.

Copyright © 2018, Texas Instruments Incorporated

Figure 11-3. Example of DMA 3 MPU Region Set Up

This will allow DMA to be able to create transfer from any location within peripheral frame to a specific allocation in system RAM to avoid corrupting the system memory RAM reserved for other tasks.

Following is the recommended generic software sequence to setup the MPU regions:

1. Make sure the bus master is idle and not sending any transaction. Please follow the bus master TRM on how to idle the bus interface. it will be different from one bus master to another.
2. Write 0xA to unlocked field LOCK of MPULOCK register (Section 11.4.2) to allow update to NMPU control registers.
3. Enable MPU error pulse event to ESM by writing 0xA to field ERRENA field of MPUCTRL2 register (Section 11.4.8). Program this step if and only if the bus master has no capability to capture the MPU transaction error from NMPU. If bus master has the ability to report transaction error, disable the ERRENA. Software will rely on bus master to trigger error event causing interrupt to the CPU.
4. Read MPUTYPE register (Section 11.4.9) to identify how many regions are implemented for this bus master in a particular device.
5. Program the MPUREGNUM register (Section 11.4.13) to indicate that MPU region number to write starting address, size, permission, and so on.
6. Program the MPUREGBASE register (Section 11.4.10) to set the base address for the particular MPU region number that was set in step 5.

Copyright © 2018, Texas Instruments Incorporated

7. Program the MPUREGSENA register (Section 11.4.11) to set the size, and enable MPU region number indicated by step 5 above. Notice that this is not yet enabling the NMPU module.
8. Program the MPUREGACR register (Section 11.4.12) to set access permission for user or privilege mode.
9. Repeat steps 5 to 8 for the remaining MPU regions available for the particular NMPU instance.
10. Write 0xA to MPUENA field of MPUCTRL1 register (Section 11.4.7) to enable NMPU to start access permission check.
11. Write 0x5 to unlocked key field LOCK of MPULOCK register (Section 11.4.2) to avoid unintentional write to NMPU configuration registers.
12. Enable bus master to start transaction. Please follow the bus master TRM on how to start the bus interface. it will be different from one bus master to another.

During application run time, if the NMPU detects a memory access violation or the functional fail safe logic detects a lock step compare error, you will be interrupted. Refer to TRM to find out which ESM group and channel the NMPU or bus master error event is mapped (based on step 3 above) and which VIM channel the ESM interrupt output is mapped.

Following is the recommended generic software sequence to find out what causes MPU error:

1. Read the MPUERRSTAT register:
   - If RERR (read error), WERR (write error), BGERR (background error), or APERR (access permission error) is set and ERRFLAG is also set, this indicates that the bus master tries to access the address location that violates the memory protection setting. This can happen due to software bug, transient fault, or permanent fault.
   - If DIAGERR (safety diagnostic error) bit is set and ERRFLAG is also set, this indicates that the 1oo1D diagnostic architect for input address masking, address translation, or mode translation has detected an error. This can happen due to transient fault or permanent fault.
2. You can further read additional information from REGION, MASTERID, or ERRFLAG bit fields of MPUERRSTAT register and MPUERRADDR register to narrow down the causes.
3. In fault case, it is up to end application to decide on whether to bring the system to safe state or ignore NMPU error or try to recover by retrying transaction if master is able to support it. If bus master does not support retry of a particular transaction, use can halt bus master, starts NMPU internal diagnostic (see Section 11.2.2.1). Assume diagnostic result passes, you can restart bus master operation. If the recover attempt still fails, you can decide to bring the system to safe state.

11.3.2 How to Use Diagnostics

Diagnostic mode can be used to verify the MPU address and access permission comparator logic working properly at either start up time or during application run time with/without error encountered. This is achieved by internal or external diagnostic mode. Entering or exiting the diagnostic mode will automatically clear the MPUERRSTAT (Section 11.4.5) and MPUERRADDR (Section 11.4.6) registers. It is recommended that you back up the values of MPUERRSTAT (Section 11.4.5) and MPUERRADDR (Section 11.4.6) registers to system RAM prior to start diagnostic during run time.

Another diagnostic mode of NMPU is for functional fail safe diagnostic. Features like input address masking, address translation and mode translation are integrated along with a critical function like memory protection, thus NMPU needs to have the hardware logic for run-time diagnostics. This logic is implemented using 1oo1D safety architecture.

Copyright © 2018, Texas Instruments Incorporated

11.3.2.1 How to Run Internal Diagnostic Mode

In internal diagnostic mode, diagnostic logic inside the NMPU module drives the input of the MPU address and access permission comparator logic. You can program the address for which comparison needs to be performed and the type of transaction (read/write and user/privilege). For every write to the MPUDIAGADDR register, an address and access permission comparison is performed and the results are stored in MPUERRSTAT and MPUERRADDR registers. ERROR output to ESM will be generated if ERRENA field in MPUCTRL2 register is set to 0xAh. The following is the recommended sequence for internal diagnostic mode:

1. User must ensure that no bus transactions from the master are going on while NMPU is in internal diagnostic mode by disabling bus master access. Please follow the bus master TRM on how to idle the bus interface. it will be different from one bus master to another.
2. Unlock the MPU registers by writing 0xA to LOCK field of MPULOCK register.
3. Disable memory protection by writing 0x5 to MPUENA key of MPUCTRL1 register.
4. Program the different MPU regions in MPUREGBASE0-7, MPUREGSENA0-7 and MPUREGACR0-7 registers.
5. In MPUDIAGCTRL register, program the INT/EXT bit as 0.
6. Enable the DIAGKEY in MPUDIAGCTRL register by writing 0xA.
7. Program the diagnostic transaction type as read/write in R/W bit in MPUDIAGCTRL register. User/Privilege mode is set in U/P bit in the same register.
8. Program the diagnostic address in MPUDIAGADDR register.
9. If there should be an access permission violation according to the diagnostic test, error flag is set.
10. Read the MPUERRSTAT and MPUERRADDR registers and verify the expected results.
11. Clear the ERRFLAG bit in MPUERRSTAT register.
12. Repeat steps 6 to 10 for different values of diagnostic address and R/W bit.
13. Exit the diagnostic mode by writing 0x5 to DIAGKEY field in MPUDIAGCTRL register.
14. Lock the MPU registers by writing 0xA to LOCK field of MPULOCK register.
15. User enables bus master. Please follow the bus master TRM on how to enable the bus interface. it will be different from one bus master to another.

Copyright © 2018, Texas Instruments Incorporated

11.3.2.2 How to Run External Diagnostic Mode

In external diagnostic mode, the actual bus master initiates the memory transaction. Address from the bus master is replaced by the address in MPUDIAGADDR register before the address reaches the address comparator logic. In this mode, both bus error response and ERROR pulse to ESM (if ERRENA field of MPUCTRL2 register is set to 0xAh) are generated for accesses that violate the access permissions. This mode is useful for a complete signal chain testing from bus master internal bus generation logic to NMPU comparator logics. The following is the recommended sequence for external diagnostic mode:

1. User must ensure that no bus transactions from the master are going on while NMPU is configuring in external diagnostic mode by disabling bus master access. Please follow the bus master TRM on how to idle the bus interface. it will be different from one bus master to another.
2. Unlock the MPU registers by writing 0xA to LOCK field of MPULOCK register.
3. Disable memory protection by writing 0x5 to MPUENA field of MPUCTRL1 register.
4. Program the different MPU regions in MPUREGBASE0-7, MPUREGSENA0-7 and MPUREGACR0-7 registers.
5. In MPUDIAGCTRL register, program the INT/EXT bit as 1.
6. Enable the DIAGKEY field of MPUDIAGCTRL register by writing 0xA.
7. Program the diagnostic address in MPUDIAGADDR register.
8. Enable memory protection by writing 0xA to MPUENA field of MPUCTRL1 register.
9. User enables bus master. Please follow the bus master TRM on how to enable the bus interface. it will be different from one bus master to another.
10. Initiate ONE bus transactions using the actual bus master.
11. Read the MPUERRSTAT and MPUERRADDR registers and verify the expected results.
12. Clear the ERRFLAG bit in MPUERRSTAT register.
13. Repeat steps 7,10, 11, 12 for different values of diagnostic address.
14. Disable memory protection by writing 0x5 to MPUENA field of MPUCTRL1 register.
15. Exit the diagnostic mode by writing 0x5 to DIAGKEY field in MPUDIAGCTRL register.
16. Lock the MPU registers by writing 0xA to LOCK field of MPULOCK register.
17. Restart the bus master functional operation. Please follow the bus master TRM on how to enable the bus interface. it will be different from one bus master to another.

Copyright © 2018, Texas Instruments Incorporated

11.4 NMPU Registers

The new memory protection unit (NMPU) registers listed in Table 11-3 are accessed through the system module register space in the Cortex-R5F CPUs memory-map. All registers are 32-bit wide and are located on a 32-bit boundary. Reads and writes to registers are supported in 8-, 16-, and 32-bit accesses. Refer to the device specific datasheet for the base address of each instance of NMPU in the device.

NOTE: If a register is not implemented, corresponding address location behaves like a reserved location, that is, reads return 0 and writes have no effect. User mode writes to NMPU registers are ignored. No error response is given for such an access. Writes to registers other than MPUERRSTAT register are ignored, when NMPU registers are locked (LOCK = 5h in MPULOCK register). No error response is given for such an access.

Table 11-3. NMPU Registers

Offset	Acronym	Register Description	Section
00h	MPUREV	MPU Revision ID Register	Section 11.4.1
04h	MPULOCK	MPU Lock Register	Section 11.4.2
08h	MPUDIAGCTRL	MPU Diagnostics Control Register	Section 11.4.3
0Ch	MPUDIAGADDR	MPU Diagnostic Address Register	Section 11.4.4
10h	MPUERRSTAT	MPU Error Status Register	Section 11.4.5
14h	MPUERRADDR	MPU Error Address Register	Section 11.4.6
20h	MPUCTRL1	MPU Control Register 1	Section 11.4.7
24h	MPUCTRL2	MPU Control Register 2	Section 11.4.8
2Ch	MPUTYPE	MPU Type Register	Section 11.4.9
30h	MPUREGBASE	MPU Region Base Address Register	Section 11.4.10
34h	MPUREGSENA	MPU Region Size and Enable Register	Section 11.4.11
38h	MPUREGACR	MPU Region Access Control Register	Section 11.4.12

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 11-5. MPU Lock Register (MPULOCK) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reserved. Reads return 0.
3-0	LOCK		MPU Register Lock Key. Lock feature prevents unintentional updates to MPU registers. Writes to registers other than MPUERRSTAT is possible only when MPU is unlocked. This field is updated only if the write data is 5h or Ah. Register writes are ignored for all other values of write data. A built-in correction logic detects single bit soft error on this field and corrects the value in the next cycle. Functionality and register read data remain the same during the correction cycle. **Read:** Returns current value of LOCK bits.
			Write in Privilege:
		5h	Writes to other MPU registers are blocked.
		Ah	Writes to other MPU registers are allowed.
		All other values	Reserved. The bits remain unchanged.

Reserved		DIAGKEY		Reserved	
R-0		R/WP-5h		R-0	

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 11-6. MPU Diagnostics Control Register (MPUDIAGCTRL) Field Descriptions

Bit	Field	Value	Description
31-19	Reserved	0	Reserved. Reads return 0.
18	U_P		User/Privilege transaction in internal diagnostic mode. This field is used only in internal diagnostic mode. **Read:** Returns the current value of U_P.
			Write in Privilege:
		0	For access permission checks, treat the transaction as user mode access.
		1	For access permission checks, treat the transaction as privilege mode access.
17	R_W		Read/Write transaction in internal diagnostic mode. This field is used only in internal diagnostic mode. **Read:** Returns the current value of R_W.
			Write in Privilege:
		0	For access permission checks, treat the transaction as read.
		1	For access permission checks, treat the transaction as write.
16	INT_EXT		Internal/External diagnostic mode. **Read:** Returns the current value of INT_EXT.
			Write in Privilege:
		0	Enable internal diagnostic mode.
		1	Enable external diagnostic mode.
15-8	Reserved	0	Reserved. Reads return 0.
7-4	DIAGKEY		Diagnostics mode key. This is the key for enabling diagnostics mode. All other diagnostic configuration fields must be programmed before enabling this key. Diagnostic mode is entered by writing Ah to this key. Entering or exiting the diagnostic mode automatically clears the MPUERRSTAT and MPUERRADDR registers. This field is updated only if the write data is 5h or Ah. Register writes are ignored for all other values of write data. A built-in correction logic detects single bit soft error on this field and corrects the value in the next cycle. Functionality and register read data remain the same during the correction cycle. **Read:** Returns the current value of DIAGKEY.
			Write in Privilege:
		5h	Diagnostics mode is disabled.
		Ah	Diagnostics mode is enabled.
		All other values	Reserved. The bits remain unchanged.
3-0	Reserved	0	Reserved. Reads return 0.

Error Profiling Controller (EPC)

This chapter describes overall functionality and how to use the Error Profiling Controller (EPC).

Topic **Page**

12.1 Overview 484
12.2 Module Operation 484
12.3 How to Use EPC 487
12.4 EPC Control Registers 488

Copyright © 2018, Texas Instruments Incorporated

12.1 Overview

The EPC is used as a diagnostic for functional safety purposes.

The primary goal of this module is to provide a unified correctable ECC error (single-bit ECC fault) profiling capability and error address cache on ECC failures in system bus memory slaves like Flash, FEE, and SRAM.

The secondary goal of this module is to provide an ECC error reporting capability for bus masters which are not natively built to manage ECC error like the interconnect.

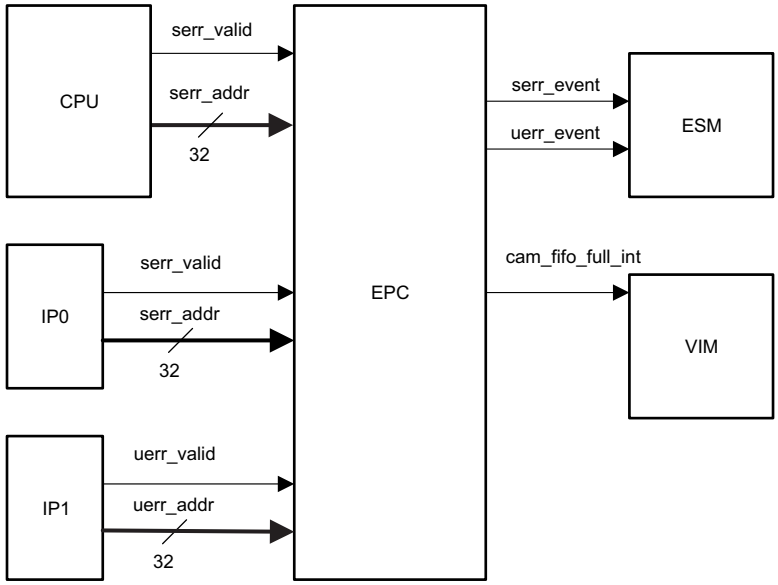
The EPC can not distinguish between memory failure and interconnect failure. A fault address may not always mean there is a true issue in the memory. EPC captures both the correctable and uncorrectable information.

The EPC supports the following features:

- Traps the correctable and uncorrectable faults from RAM, CPU, and Interconnect.
- For correctable fault, EPC will keep track of unique addresses through the usage of Content Address Memory (CAM).
- Allow CPU accessing CAM to set or clear any CAM entry index and/or content during execution run time as well as diagnosing the CAM.
- Trigger error event to Error Signaling Module (ESM) and keep track of error in status register for user query.

12.2 Module Operation

Figure 12-1 shows the typical usage of EPC in device architecture. In the EPC chapter, the CPU, RAM, or Interconnect is referred to as IP. The Error Profiling Module section in the Architecture chapter indicates which IP correctable and uncorrectable event are hooked up to EPC. Each IP can provide either or both correctable and uncorrectable fault event to EPC. The EPC chapter will mention IP correctable or uncorrectable fault event with generic description of how EPC process these fault events.



EPC captures the uncorrectable address from IP that are not natively built to manage ECC error like interconnect and triggers uerr_event to ESM. See Section 12.2.1 for more details.

EPC performs error profiling on the correctable fault and trigger serr_event to ESM if the address of the correctable fault is not part of the CAM and SERRENA control bits are set to enable values. Detail description of error profiling definition is described in Section 12.2.2. Each single fault correctable IP has a FIFO to buffer correctable fault address input. Following is the behavior of FIFO and CAM operation:

1. If FIFO overflow happens on a particular ECC correctable IP, EPC will set the corresponding FIFO Overflow Bit in the Overflow Status Register (OVRFLWSTAT) and trigger serr_event.
2. If any of the FIFOs is full (any FIFOFULLSTAT(x) is set), EPC will trigger the cam_fifo_full_int port if CAM/FIFO full interrupt enable (EPCCNTRL(24)) is set.
3. If CAM indexes are all occupied, EPC will set the CAM Full Bit in EPCERRSTAT register and trigger the cam_fifo_full_int port if CAM/FIFO full interrupt enable is set.
4. If CAM overflow happens, EPC will set CAM overflow status bit (cam ovflw) in EPCERRSTAT register.
5. You can access CAM content and CAM index during functional and diagnostic run time.

Copyright © 2018, Texas Instruments Incorporated

Figure 12-1. EPC System Block Diagram

12.2.1 Uncorrectable Fault Operation

EPC will capture full 32-bit addresses of uncorrectable fault from interconnect and RAM IP modules to UERRADDR_(0,1) registers and set the corresponding uncorrectable status bit in UERRSTAT register. The first uncorrectable address from RAM and interconnect IP will be captured to the corresponding UERRADDR_(0,1) and frozen until CPU in privilege mode write clears to the corresponding UERRSTAT bit.

Whenever any status bit in ERRSTAT just got set by the presence of a new uncorrectable fault, EPC will trigger uncorrectable fault event to ESM. The bits in UERRSTAT can only be cleared by device power on reset or CPU write clears in privilege mode.

12.2.2 Correctable Fault Operation

12.2.2.1 Functional Mode

CPU, Interconnect, and RAM IP can trigger correctable fault event to EPC. The EPC provides a 4-entry FIFO to each of these IP(s) to capture correctable event and its 64-bit aligned addresses.

A FIFO full condition happens when all 4 entries of a particular FIFO are occupied. In this case, the corresponding FIFO full status bit of the IP will be set in FIFOFULLSTAT register. An interrupt will be generated if CAMFIFOFULLENA bit is set in EPCCNTRL register.

A FIFO overflow can happen when all entries are occupied and there is a new correctable fault event just arrives to the same FIFO. In this case, the new correctable fault event and address will be discarded, but the overflow bit remained to be set. If the SERRENA bits in EPCCNTRL register are enabled, the single-bit error correctable fault event will be triggered to ESM.

A FIFO full or overflow interrupt indicates to you that there is an abnormal condition on the number of correctable faults happening to the particular IP. It is up to application software to handle this situation by either putting the system in safe stage if the IP causing full or overflow interrupt happens to be a critical IP in safety application or doing extra diagnostic of the corresponding IP memory during diagnostic time. You can write clears the corresponding FIFO full or overflow status bit in privilege mode.

Copyright © 2018, Texas Instruments Incorporated

The 64-bit aligned address of the correctable fault from each IP FIFO is sent to the CAM to check if the correctable fault is unique or repetitive. If it is a repetitive address for the correctable fault, then the correctable fault and its address are discarded and no further indication to the CPU. If it is a unique address, then the address will be remembered in the CAM content and CAM index will be set to occupied. It is software configurable to raise an error event to ESM if SERRENA bits in EPCCNTRL are enable.

If all CAM indexes are occupied, EPC will set the CAM full status bit in EPCERRSTAT register and trigger an interrupt to VIM if CAMFIFOFULLENA bit in EPCCNTRL register is set. You can inspect CAM and set its indexes to available.

If all CAM indexes are occupied and there is a new correctable fault event to be checked, the EPC will set the CAM overflow status bit in EPCERRSTAT register and trigger an error event to ESM if correctable error event enable bits are set in EPCCNTRL register. The CAM content and index are not updated when CAM overflow happens.

Reading a CAM index value of 5h indicates the CAM entry is available and reading a value of Ah indicates the CAM entry is occupied. You can also inspect the number of CAM indexes that are still in available state by reading the CAMAVAILSTAT register.

CAM content and index can only be updated in privilege mode.

In functional mode, CPU can only set CAM index to available state but not occupied state. Occupied state setting by CPU will be ignored.

CPU can also update the CAM content. In this case, once the CAM content is updated, the CAM index will auto set to occupied state, but there is no correctable error event generation to ESM. This is mainly used as a way to avoid correctable error event generation for hard fault on single (correctable) bit error address in functional mode. An example usage would be: Assume address 0x0800_0000 has a hard fault single-bit error in the RAM. You can write 0x0800_0000 to the EPC CAM content. This write will update the corresponding CAM index to “occupied” by EPC hardware. You can avoid EPC generation of single-bit error event every time the CPU accessing address 0x0800_0000.

12.2.2.2 Diagnostic Mode

EPC allows you to diagnose the CAM content, CAM index, and correctable event generation to ensure the CAM operates correctly and to avoid latent fault.

You need to set DIAG_ENA_KEY in EPCCNTRL register to Ah to enter diagnostic mode.

Once in diagnostic mode, you can change any CAM index to available or occupied state. Setting all CAM indexes to occupied will result in CAM full status bit to be set in EPCCNTRL register. In this case, EPC will generate the CAM full interrupt if CAM/FIFO full interrupt enable is set. The NUMCAMAVAIL bits of CAMAVAILSTAT will also reflect the number of CAM index available when you change the CAM index values between available and occupied.

Writes to CAM content will also set the corresponding CAM index to occupied and trigger correctable error event to ESM. This is done to test the signal chain in CAM content update for unique address and triggering correctable event in functional mode.

12.3 How to Use EPC

12.3.1 Functional Mode

Following steps are the recommended sequences to initialize EPC:

1. Set up correct values for SERRENA and CAMFIFO FULL ENA bits in EPCCNTRL. Setting SERRENA will enable correctable error event generation to ESM. Setting CAMFIFO FULL ENA will enable CAM full or FIFO full interrupt to the CPU. You need to set these values in according to their safety application requirement.
2. Read CAMAVAILSTAT to ensure that all CAM indexes are available after system reset.

On CAM or FIFO full interrupt, following sequences are recommended to query the EPC:

1. Read EPCERRSTAT and FIFOFULLSTAT to determine if this is CAM or FIFO full.
   a. If it is FIFO full, the FIFOFULLSTAT indicates which IP FIFO is full so you can make a decision on whether to put the system in safe state if the particular IP happens to be a critical IP in safety application or doing extra diagnostic of the corresponding IP RAM during diagnostic time. Clear the FIFO full by write clear to the FIFOFULLSTAT register.
   b. If it is CAM full, you need to read CAM content to find out if most of the correctable fault happens to be in the same IP or scatter among IP in order to take decision on whether to put the system in safe state or decides to run certain RAM test during diagnostic time. You can also keep track of the correctable fault in system RAM in order to clear the CAM index to avoid CAM overflow condition.

On correctable error event or CAM overflow or FIFO overflow from ESM interrupt CPU, following sequences are recommended to query the EPC:

1. Read EPCERRSTAT and OVRFLWSTAT registers to determine if this is CAM or FIFO overflow or a registration of new correctable fault event in CAM.
   a. If it is FIFO overflow, the OVRFLWSTAT indicates which IP FIFO has overflow so you can make decision on whether to put the system in safe state if the particular IP happens to be a critical IP in safety application or doing extra diagnostic of the corresponding IP RAM during diagnostic time. Clear the FIFO overflow by write clear to the OVRFLWSTAT register.
   b. If it is CAM overflow, that means you do not service the CAM full interrupt in time. You need to read CAM content to find out if most of the correctable fault happens to be in the same IP or scatter among IP in order to take decision on whether to put the system in safe state or decides to run certain RAM test during diagnostic time. You can also keep track of the correctable fault in system RAM in order to clear the CAM index to avoid CAM overflow condition.
   c. If it is none of the two above cases, then it is a new correctable fault event register on CAM. You can read the CAM index registers and CAM content registers to determine which IP RAM or RAM location that has the correctable fault and does a quick diagnose of that RAM location by backing up location content, write and read back new RAM value. If it is a transient fault, restores RAM backup data and clear the CAM index. Otherwise, mark it as permanent fault by not clearing the index to available so that it does not generate correctable error event again.

On uncorrectable error event, following sequences are recommended to query the EPC:

1. Read UERRSTAT register to determine which IP_(n) causing uncorrectable fault.
2. Read the corresponding UERR_ADDR_(n) to determine the location of the fault.
3. Diagnose the corresponding location to determine if this is a permanent or transient fault. Depending on the criticality of this uncorrectable fault in safety application, it is up to you to bring the system to safe state or not.

Copyright © 2018, Texas Instruments Incorporated

12.3.2 CAM Diagnostic Mode

In order to test the CAM logic and error event generation functionality, you need to diagnose the CAM at diagnostic time in their control loop.

Following sequences are recommended to diagnose the CAM and error event generation:

1. Configure EPC in diagnostic mode by setting the DIAG_ENA_KEY to Ah in EPCCNTRL register.
2. Backing up the CAM content and CAM index to system RAM.
3. Change CAM index to available state from occupied state and vice versa and check the number of CAM available status correctly reflected in CAMAVAILSTAT register as well as the CAM index registers correctly reflecting the new state.
4. Write to CAM content of any available index and should observe a correctable error event set in ESM as well as CAM index set to occupied.
5. Restore the CAM content and CAM index values.
6. Exit diagnostic mode by writing 5h to DIAG_ENA_KEY.

12.4 EPC Control Registers

The error profiling controller registers listed in Table 12-1 are accessed through the system module register space in the Cortex-R5F CPUs memory-map. All registers are 32-bit wide and are located on a 32-bit boundary. Reads and writes to registers are supported in 8-, 16-, and 32-bit accesses. The base address for the control registers is FFFF 0C00h.

Table 12-3. EPC Control Register (EPCCNTRL) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reserved. Reads return 0.
24	CAM/FIFO_FULL_ENA		CAM or FIFO full interrupt enable. If this bit is set and CAM is full, CAM Full Interrupt is generated.
			Read:
		0	CAM/FIFO full interrupt is disabled.
		1	CAM/FIFO full interrupt is enabled.
			Write in Privilege:
		0	Disable CAM/FIFO full interrupt.
		1	Enable CAM/FIFO full interrupt.
23-12	Reserved	0	Reserved. Reads return 0.
11-8	DIA_ENA_KEY		CAM diagnostic enable key. These bits (when enabled) allow the CPU to access the CAM content to clear or set any entry (CAM index) or write any pattern to CAM content.
			Internal RTL will implement self-correction logic to avoid single bit flipping.
			Read:
		5h	CAM diagnostic is disabled.
		Ah	CAM diagnostic is enabled.
		All other values	Reserved
			Write in Privilege:
		5h	CAM diagnostic is disabled.
		Ah	CAM diagnostic is enabled.
		All other values	Reserved
7-4	Reserved	0	Reserved. Reads return 0.
3-0	SERRENA		Single (correctable) bit error event enable. These bits (when enable) cause EPC to generate the serr_event if there is a correctable ECC fault address arrives from one of the EPC-IP interface and the CAM has an empty entry. These bits also allow EPC to generate the serr_event if there is a correctable ECC fault address arrives from one of the EPC-IP interface and the CAM is full. In this case, CAM FULL status bit is set in EPCERRSTAT.
			Internal RTL will implement self-correction logic to avoid single bit flipping.
			Read:
		5h	serr_event generation is disabled.

Table 12-4. Uncorrectable Error Status Register (UERRSTAT) Field Descriptions

Bit	Field	Value	Description
31-2	Reserved	0	Reserved. Reads return 0.
1-0	UE*n*		Uncorrectable ECC Fault Status Bit for interface *n*. Each bit corresponds to one uncorrectable EPC-IP interface. If the IP triggers uncorrectable error, one of these bits gets set. Once it is set, it can only be cleared by power-on reset or CPU write-clear in privilege mode or by reading the corresponding UERRADDR register. Any of these bits set causes an uncorrectable error event (uerr_event) to be triggered to ESM. The number of implemented bits depends on the number of implemented EPC IP uncorrectable address ports. Unimplemented bits are reserved and are not writable. Reserved bits are read as 0. **Read:**
		0	Uncorrectable ECC fault status bit is not active for interface *n*.
		1	Uncorrectable ECC fault status bit is active for interface *n*.
			Write in Privilege:
		0	No effect.
		1	Clear this flag bit.

Table 12-9. Uncorrectable Error Address Register n (UERR_ADDR) Field Descriptions

Bit	Field	Description
31-0	UERR_ADDR	Register *n* corresponds to uncorrectable port *n*. The number of uncorrectable ports is configured through the generic parameter: Number of EPC uncorrectable ports. This 32-bit register captures the uncorrectable address error from each EPC-IP uncorrectable interface. Once EPC-IP interface receives the uerr_valid_x, the corresponding address is captured and frozen. CPU read (privilege mode) of this address unfreezes this register. EMUDBG read access is non-intrusive (not unfreeze). Power-on reset, write-clear to the corresponding UERRSTAT bit or reading of the ERRADDR register also unfreezes this register for each interface. Unfreeze means that the register content can be updated whenever there is the next uncorrectable error address becomes active on this interface.

12.4.9 CAM Content Update Register n (CAM_CONTENT)

CPU Compare Module for Cortex-R5F (CCM-R5F)

This chapter describes the CPU compare module for the ARM® Cortex®-R5F (CCM-R5F). This device implements two instances of the Cortex-R5F CPU that are running in lockstep to detect faults that may result in unsafe operating conditions. The CCM-R5F detects faults and signals them to an error signaling module (ESM).

NOTE: In general, the R5F term is used when referencing the Cortex-R5F CPU used in the Hercules family of devices; however, the floating-point functionality is a device-specific option and may not be included in some devices. Consult your device-specific datasheet to determine which core is included on your specific device being used.

Topic **Page**

13.1 Overview **498**
13.2 Module Operation **499**
13.3 Control Registers **507**

Copyright © 2018, Texas Instruments Incorporated

13.1 Overview

Safety-critical applications require run-time detection of faults in critical components in the device such as the Central Processing Unit (CPU) and the Vectored Interrupt Controller Module (VIM). For this purpose, the CPU Compare Module for Cortex-R5F (CCM-R5F) compares the core bus outputs of two Cortex-R5F CPUs running in a 1oo1D (one-out-of-one, with diagnostics) lockstep configuration. This microcontroller also implements two VIM modules in 1oo1D (one-out-of-one, with diagnostic) lockstep configuration. Any difference in the core compare bus outputs of the CPUs or the VIMs is flagged as an error. For diagnostic purposes, the CCM-R5F also incorporates a self-test capability to allow for boot time checking of hardware faults within the CCM-R5F itself.

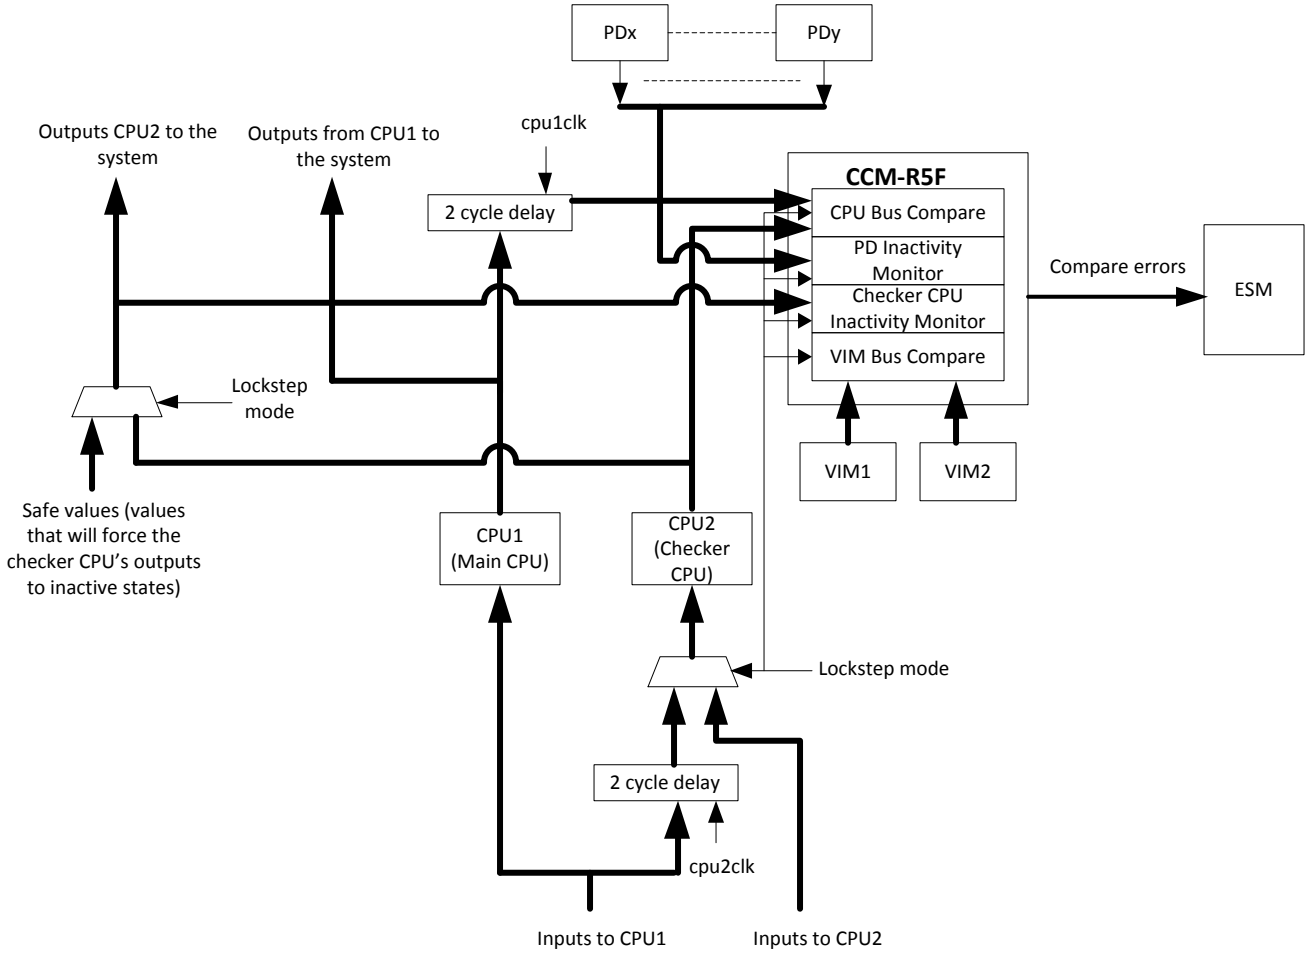
In addition to comparing the CPU's and VIM's outputs for fault detection during run-time, the CCM-R5F also incorporates two additional run-time diagnostic features.

The first additional measure is the Checker CPU Inactivity Monitor which will monitor the checker CPU's key bus signals to the interconnect. When the two CPUs are in lockstep configuration, several key bus signals from the checker CPU which would have indicated a valid bus transaction to the interconnect on the microcontroller will be monitored. A list of the signals to be monitored is provided in Table 13-5. These signals from the checker CPU are expected to be inactive. All transactions between the lockstep CPUs and the rest of the system should only go through the main CPU. Any signals which indicate activity will be flagged as an error.

The second feature is the Power Domain (PD) Inactivity Monitor. Similar to the Checker CPU Inactivity Monitor in concept, the Power Domain Inactivity Monitor will monitor key bus signals for bus masters residing in power domains which are turned off. When a power domain is turned off, the boundary of the power domain is isolated from the rest of the system. Bus signals which would have indicated a valid bus transaction onto the interconnect are monitored. Any signals which indicate active state will be flagged as an error.

13.1.1 Main Features

The main features of the CCM-R5F are:



- Run-time detection of faults
  - Run-time compare of CPU's outputs
  - Run-time compare of VIM's outputs
  - Run-time inactivity monitor on the checker CPU's bus signals to the interconnect
  - Run-time inactivity monitor on the power domains' bus signals to the interconnect
- self-test capability
- error forcing capability

13.1.2 Block Diagram

Figure 13-1 shows the interconnect diagram of the CCM-R5F with the two Cortex-R5F CPUs and the two VIMs. The core bus outputs of the CPUs are compared in the CCM-R5F. To avoid common mode impacts, the signals of the CPUs to be compared are temporally diverse. The output signals of the master CPU are delayed 2 cycles while the input signals of checker CPU are delayed 2 cycles. The two cycle delay strategy is also deployed between the two VIM modules. While in lockstep mode, the checker CPU's output signals to the system are clamped to inactive safe values. Key signals which would have indicated a valid bus transaction to the interconnect are monitored by the CCM-R5F. The same approach is used for the key power domains if inactive signals indicate that bus masters inside these power domains are asserting valid bus transactions.

Figure 13-1. Block Diagram

13.2 Module Operation

As described in Section 13.1, there are four different run-time diagnostics supported by the CCM-R5F. The CCM-R5F compares the core bus outputs of the master and checker Cortex-R5F CPUs on the microcontroller and signals an error on any mismatch. This comparison is started 6 CPU clock cycles after the CPU comes out of reset to ensure that CPU output signals have propagated to a known value after reset. Once comparison is started, the CCM module continues to monitor the outputs of the two CPUs without any software intervention. If an error is detected by the CCM-R5F, a software handler is necessary to implement the appropriate response to the error dependent on application needs. The module principles of operation are applicable to both the CPU output compare as described above as well as to the VIM output compare.

Copyright © 2018, Texas Instruments Incorporated

13.2.1 CPU/VIM Output Compare Diagnostic

CPU / VIM Output Compare Diagnostic can run in one of the following four operating modes:

1. Active compare lockstep mode
2. Self-test
3. Error forcing
4. Self-test error forcing

The operating mode can be selected by writing a dedicated key to the key register (MKEYx) of the corresponding diagnostic.

NOTE: MKEY1 and MKEY2 are used to select the operating mode for the CPU Output Compare Diagnostic and VIM Output Compare Diagnostic, respectively.

13.2.1.1 Active Compare lockstep Mode

This is the default mode on start-up. In lockstep mode, the bus output signals of both CPUs and VIMs are compared. A difference in the CPU compare bus outputs is indicated by signaling an error to the ESM, which sets the error flag "CCM-R5F - CPU compare" and "CCM-R5F - VIM compare", respectively.

- CPU types of output signals to be compared:
  - Global signals
  - Interrupt signals
  - All L1 cache interface signals
  - All cache coherency signals
  - All L1 TCM interface signals
  - All L2 AXI interface signals
  - ETM interface signals
  - FPU signals
  - All ACP interface signals
  - All AXI Peripheral port interface signals
  - All AHB Peripheral port interface signals
  - All status and control signals
- VIM output signals to be compared:
  - nFIQ
  - nIRQ
  - IRQADDRV
  - IRQVECTADDR

NOTE: The CPU compare error asserts “CCM-R5F self-test error” flag as well. By doing this, the CPU compare error has two paths (“CCM-R5F - CPU compare” and “CCM-R5F self-test error” flag) to the ESM, so that even if one of the paths fails, the error is still propagated to the ESM. This is also true for "CCM-R5F - VIM compare" error flag.

Not all internal registers of the Cortex-R5F CPU have fixed values upon reset. To avoid an erroneous CCM-R5F compare error, the application software needs to ensure that the CPU registers of both CPUs are initialized with the same values before the registers are used, including function calls where the register values are pushed onto the stack.

Copyright © 2018, Texas Instruments Incorporated

13.2.1.2 Self-Test Mode

In self-test mode, the CCM-R5F checks itself for faults. During self-test, the compare error module output signal is deactivated. Any fault detected inside the CCM-R5F will be flagged by ESM error “CCM-R5F - self-test”.

In self-test mode, the CCM-R5F automatically generates test patterns to look for any hardware faults. If a fault is detected, then a self-test error flag is set, a self-test error signal is asserted and sent to the ESM, and the self-test is terminated immediately. If no fault is found during self-test, the self-test complete flag is set. In both cases, the CCM-R5F CPU / VIM Output Compare Diagnostic remains in self-test mode after the test has been terminated or completed, and the application needs to switch the CCM-R5F mode by writing another key to the mode key register (MKEY1 or MKEY2 depending which diagnostic is selected for self-test). During the self-test operation, the compare error signal output to the ESM is inactive irrespective of the compare result.

There are two types of patterns generated by CCM-R5F during self-test mode:

1. Compare Match Test
2. Compare Mismatch Test

CCM-R5F first generates Compare Match Test patterns, followed by Compare Mismatch Test patterns. Each test pattern is applied on both CPU signal inputs of the CCM-R5F’s compare block and clocked for one cycle. The duration of self-test for CPU Output Compare Diagnostic is 4947 CPU clock cycles (GCLK1) and 151 system peripheral clock cycles (VCLK) for VIM Output Compare Diagnostic.

NOTE: During self-test, both CPUs can execute normally, but the compare logic will not be checking any CPU signals. Also during self-test, only the compare unit logic is tested and not the memory-mapped register controls for the CCM-R5F. The self-test is not interruptible.

Self-test of all different diagnostics can be run at the same time.

13.2.1.2.1 Compare Match Test

During the Compare Match Test, there are four different test patterns generated to stimulate the CCM-R5F. An identical vector is applied to both input ports at the same time expecting a compare match. These patterns cause the self-test logic to exercise every CPU compare bus output signal in parallel. If the compare unit produces a compare mismatch then the self-test error flag is set, the self-test error signal is generated, and the Compare Match Test is terminated.

The four test patterns used for the Compare Match Test are:

- All 1s on both CPU / VIM signal ports
- All 0s on both CPU / VIM signal ports
- 0xAs on both CPU / VIM signal ports
- 0x5s on both CPU / VIM signal ports

These four test patterns will take four clock cycles to complete. Table 13-1 illustrates the sequence of Compare Match Test.

Table 13-1. Compare Match Test Sequence

CPU 1 (Main CPU) Signal Position									CPU 2 (Checker CPU) Signal Position									Cycle
n:8	7	6	5	4	3	2	1	0	n:8	7	6	5	4	3	2	1	0	
1s	1	1	1	1	1	1	1	1	1s	1	1	1	1	1	1	1	1	0

Copyright © 2018, Texas Instruments Incorporated

13.2.1.2.2 Compare Mismatch Test

During the Compare Mismatch Test, the number of test patterns is equal to twice the number of CPU output signals to compare in lockstep mode. An all 1s vector is applied to the CCM-R5F's CPU1 / VIM1 input port and the same pattern is also applied to the CCM-R5F's CPU2 /VIM2 input port but with one bit flipped starting from signal position 0. The un-equal vector will cause the CCM-R5F to expect a compare mismatch at signal position 0, if the CCM-R5F logic is working correctly. If, however, the CCM-R5F logic reports a compare match, the self-test error flag is set, the self-test error signal is asserted, and the Compare Mismatch Test is terminated.

This Compare Mismatch Test algorithm repeats in a domino fashion with the next signal position flipped while forcing all other signals to logic level 1. This sequence is repeated until every single signal position is verified on both CPU signal ports.

The Compare Mismatch Test is terminated if the CCM-R5F reports a compare match versus the expected compare mismatch. This test ensures that the compare unit is able to detect a mismatch on every CPU signal being compared. Table 13-2 illustrates the sequence of Compare Mismatch Test. There is no error signal sent to ESM if the expected errors are seen with each pattern.

Table 13-2. CPU / VIM Compare Mismatch Test Sequence

CPU 1 (Main CPU) Signal Position											CPU 2 (Checker CPU) Signal Position										Cycle
n	n–1:8		7	6	5	4	3	2	1	0	n	n–1:8		7	6	5	4	3	2	1	0	
1	1	1s	1	1	1	1	1	1	1	1	1	1	1s	1	1	1	1	1	1	1	0	0
1	1	1s	1	1	1	1	1	1	1	1	1	1	1s	1	1	1	1	1	1	0	1	1
1	1	1s	1	1	1	1	1	1	1	1	1	1	1s	1	1	1	1	1	0	1	1	2

13.2.1.3 Error Forcing Mode

In error forcing mode, a test pattern is applied to the CPU / VIM related inputs of the CCM-R5F compare logic to force an error in the compare error output signal of the compare unit. Depending if error forcing mode is applied to the CPU Output Compare Diagnostic or VIM Output Compare Diagnostic, the ESM error flag “CCM-R5F - CPU compare” or “CCM-R5F - VIM compare” is expected after the error forcing mode completes. As a side effect, the “CCM-R5F self-test error” flag is also asserted whenever the CPU compare error is asserted.

Error forcing mode is similar to the Compare Mismatch Test operation of self-test mode in which an un-equal vector is applied to the CCM-R5F CPU signal ports. The error forcing mode forces the compare mismatch to actually assert the compare error output signal. This ensures that a fault in the path between CCM-R5F and ESM is detected.

Only one hardcoded test pattern is applied into CCM-R5F during error forcing mode. A repeated 0x5 pattern is applied to CPU1 / VIM1 signal port of CCM-R5F input while a repeated 0xA pattern is applied to the CPU2 / VIM2 signal port of CCM-R5F input. The error forcing mode takes one cycle to complete. Hence, the failing signature is presented for one clock cycle. After that, the mode is automatically switched to lockstep mode. The key register (MKEY1 for CPU output compare and MKEY2 for VIM output compare) will indicate the lockstep key mode once it is switched to lockstep mode. During the one cycle required by the error forcing test, the CPU / VIM output signals are not compared. The user should expect the ESM to trigger a response (report the CCM-R5F fail). If no error is detected by the ESM, then a hardware fault is present.

13.2.1.4 Self-Test Error Forcing Mode

In self-test error forcing mode, an error is forced at the self-test error signal. The compare unit is still running in lockstep mode and the key is switched to lockstep after one clock cycle. The ESM error flag “CCM-R5F - self-test” is expected after the self-test error forcing mode completes. Once the expected errors are seen, the application can clean the error through the ESM module.

Table 13-3 shows what error signals and flags are asserted in different operating mode. The behavior of different modes in this table for CPU compare is also valid for other diagnostics such as VIM compare, Checker CPU Inactivity Monitor and Power Domain monitor.

Table 13-3. Error Flags and Error Signals Generation in Each Mode

Mode	Key	Self Test Error Signal	Compare Error Signal	CMPE	STC	STET	STE
Active Compare Lockstep	0000	Enabled	Enabled	Enabled	Disabled	Disabled	Disabled
Self-Test	0110	Enabled	Disabled	Disabled	Enabled	Enabled	Enabled
Error Forcing	1001	Error	Error	Disabled	Disabled	Disabled	Disabled
Self-Test Error Forcing	1111	Error	Enabled	Enabled	Disabled	Disabled	Disabled

13.2.2 CPU Input Inversion Diagnostic

There is another way to intentionally create a mismatch between the two CPUs' outputs as a diagnostic test to self-test the CCM-R5F's CPU Output Compare Diagnostic block. Before the CPU1's outputs are taken to the CCM-R5F, eight of the output signals are first exclusive-ORed bitwise with the 8-bit POLARITYINVERT register. After reset, the default value of the POLARITYINVERT register is all zeros. The resultant values of the 8 signals after the XOR logic with the POLARITYINVERT register will still be the same as the original 8 signal values. However, by programming the POLARITYINVERT to a non-zero values it will have the effect to invert the signal values. This intentional inversion on the inputs to the CCM-R5F will cause the CPU Output Compare Diagnostic to detect a compare error. See Figure 13-2 for illustration.

Figure 13-2. CPU Input Inversion Scheme

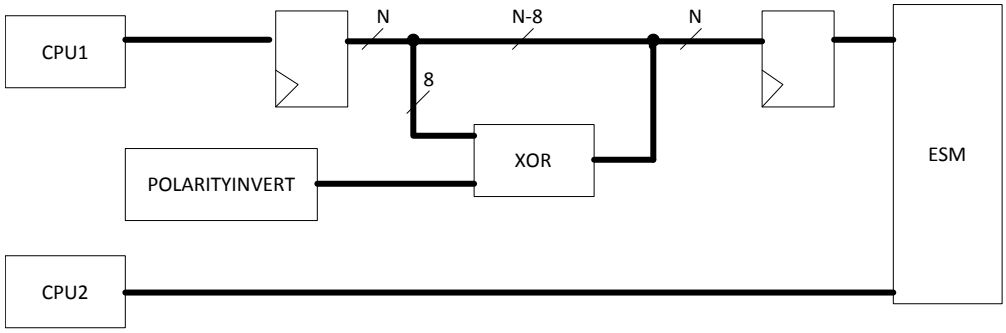

Table 13-4. CPU1 (Main CPU) Signals Being Inverted Before Being Compared

Signals	Remark
AWVALIDM	Indicates write address and control are valid
ARVALIDM	Indicates write address and control are valid
AWVALIDP	Indicates write address and control are valid
ARVALIDP	Indicates write address and control are valid
HTRANSP[1:0]	Indicates write address and control are valid

13.2.3 Checker CPU Inactivity Monitor

Similar to the CPU / VIM Output Compare Diagnostic, the Checker CPU Inactivity Monitor can also run in one of the following four operating modes:

1. Active compare
2. Self-test
3. Error forcing
4. Self-test error forcing

The operating mode can be selected by writing a dedicated key to the key register (MKEY3).

13.2.3.1 Active Compare Mode

This is the default mode on start-up. In this mode, several key bus signals such as the bus valid control signals from the checker CPU that would have indicated a valid bus transaction onto the interconnect are compared against their clamped safe values. While the two CPUs are in lockstep configuration, the outputs of the checker CPU are supposed to clamp to the inactive state that is all zeros. A difference between the checker CPU compare bus outputs and their respective inactive states is indicated by signaling an error to the ESM which sets the error flag "CCM-R5F - CPU1 AXIM Bus Monitor Failure".

Table 13-5. Checker CPU Signals to Monitor

Signals	Remark
AWVALIDM	When asserted, indicates address and control are valid on the Checker CPU's AXI master port for write transaction.
ARVALIDM	When asserted, indicates address and control are valid on the Checker CPU's AXI master port for read transaction.
AWVALIDP	When asserted, indicates address and control are valid on the Checker CPU's AXI peripheral port for write transaction.
ARVALIDP	When asserted, indicates address and control are valid on the Checker CPU's AXI peripheral port for read transaction.
BVALIDS	When asserted, indicates that a valid write response is available on the Checker CPU's AXI slave port for write transaction
RVALIDS	When asserted, indicates address and control are valid on the Checker CPU's AXI slave port for read transaction

13.2.3.2 Self-Test Mode

Similar to the other self-test described for CPU / VIM Output Compare Diagnostic, the Checker CPU Inactivity Monitor can be placed in self-test mode. In self-test mode, the CCM-R5F checks the Checker CPU Inactivity Monitor itself for faults. During self-test, the compare error module output signal is deactivated. Any fault detected inside the CCM-R5F will be flagged by ESM error “CCM-R5F - self-test”.

In self-test mode, the CCM-R5F automatically generates test patterns to look for any hardware faults. If a fault is detected, then a self-test error flag is set, a self-test error signal is asserted and sent to the ESM, and the self-test is terminated immediately. If no fault is found during self-test, the self-test complete flag is set. In both cases, the CCM-R5F Checker CPU Inactivity Monitor Diagnostic remains in self-test mode after the test has been terminated or completed, and the application needs to switch the CCM-R5F mode by writing another key to the mode key register (MKEY3). During the self-test operation, the compare error signal output to the ESM is inactive irrespective of the compare result.

There are also two types of patterns generated by CCM-R5F during self-test mode for Check CPU Inactivity Monitor. The difference here is the number of test patterns applied during self-test.

i. Compare Match Test
ii. Compare Mismatch Test

CCM-R5F first generates Compare Match Test patterns, followed by Compare Mismatch Test patterns.

Copyright © 2018, Texas Instruments Incorporated

13.2.3.2.1 Compare Match Test

Since the comparison is done against the clamped values, and all compared signals are clamped to zero, only one test pattern is applied for the compare match test. A pattern of all-zeros are applied for the compare match test. The test will take one cycle. If the compare unit produces a compare mismatch then the self-test error flag is set, the self-test error signal is generated, and the Compare Match Test is terminated.

13.2.3.2.2 Compare Mismatch Test

During the Compare Mismatch Test, the number of test patterns is equal to the number of bus signals on the checker CPU to be monitored. There are a total of 6 signals being monitored on the checker CPU's level 2 interface and hence it takes 6 test patterns for the mismatch test. The mismatch test will take a total of 6 cycles to complete. An all 0's test vector is applied to the CCM-R5F's but with one bit flipped starting from signal position 0. The un-equal vector will cause the CCM-R5F to expect a compare mismatch at signal position 0, if the CCM-R5F logic is working correctly. If, however, the CCM-R5F logic reports a compare match, the self-test error flag is set, the self-test error signal is asserted, and the Compare Mismatch Test is terminated.

This Compare Mismatch Test algorithm repeats in a domino fashion with the next signal position flipped while forcing all other signals to logic level 0. This sequence is repeated until every inactivity monitor signal position is verified on the checker CPU .

Table 13-6 shows the sequence of Compare Mismatch Test. There is no error signal sent to ESM if the expected errors are seen with each pattern.

Table 13-6. Checker CPU Inactivity Monitor Compare Mismatch Test

Signal Position						
5	4	3	2	1	0	Cycle
0	0	0	0	0	1	0
0	0	0	0	1	0	1
0	0	0	1	0	0	2
0	0	1	0	0	0	3
0	1	0	0	0	0	4
1	0	0	0	0	0	5

13.2.3.3 Error Forcing Mode

In error forcing mode, a test pattern of all 1's is applied to the check CPU's compare logic to force an error in the compare error output signal of the compare unit. The ESM error flag "CCM-R5F - CPU1 AXIM Bus Inactivity failure" is expected after the error forcing mode completes. As a side effect, the "CCM-R5F self-test error" flag is also asserted whenever the CPU compare error is asserted.

The error forcing mode takes one cycle to complete. Hence, the failing signature is presented for one clock cycle. After that, the mode is automatically switched to active compare mode. The key register (MKEY3) will indicate the active compare mode once it is switched to active compare mode. During the one cycle required by the error forcing test, the checker CPU Inactivity Monitor is deactivated. User should expect the ESM to trigger a response (report the CCM-R5F fail). If no error is detected by ESM, then a hardware fault is present.

13.2.3.4 Self-Test Error Forcing Mode

In self-test error forcing mode, an error is forced at the self-test error signal. The compare unit is still running in active compare mode and the key is switched to active compare after one clock cycle. The ESM error flag "CCM-R5F - self-test" is expected after the self-test error forcing mode completes. Once the expected errors are seen, the application can clean the error through the ESM module.

Copyright © 2018, Texas Instruments Incorporated

13.2.4 Power Domain Inactivity Monitor

The Power Domain Inactivity Monitor is very similar to the Checker CPU Inactivity Monitor in concept. When a power domain is turned off, its outputs are isolated from the rest of the system. The outputs are clamped to inactive safe values. Depending on the signals, the clamp value of a signal may be 0 or 1. Some bus masters may be residing in the turned off power domains. Key bus signals from the power domains which would have indicated that the bus master is generating a valid bus transaction are compared against their clamped values.

The Power Domain Inactivity Monitor Diagnostic can also run in one of the following four operating modes:

1. Active compare
2. Self-test
3. Error forcing
4. Self-test error forcing

The operating mode can be selected by writing a dedicated key to the key register (MKEY4).

13.2.4.1 Active Compare Mode

This is the default mode on start-up.

In this mode, several critical bus signals such as the bus request control signals from the power domains which would have indicated a valid bus transaction onto the interconnect are compared against their clamped safe values. If a power domain is turned off, the outputs of the power domain are expected to clamp to the inactive states. A difference between the power domain compare bus outputs and their respective inactive states is indicated by signaling an error to the ESM which sets the error flag "CCM-R5F - Power Domain Monitor Failure". In addition, the corresponding bus masters for which the compare block detected the monitor failure are also captured in the CCMPDSTAT0 register.

Self-test mode, Error forcing mode and Self-test error forcing mode for Power Domain Inactivity Monitor Diagnostic are the same as Checker CPU Inactivity Monitor Diagnostic. See Section 13.2.3.2, Section 13.2.3.3, and Section 13.2.3.4 for details.

13.2.5 Operation During CPU Debug Mode

Certain debug operations place the CPU in a halting debug state where the code execution is halted. Because halting debug events are asynchronous, there is a possibility for the debug requests to cause loss of lockstep. CCM-R5F will disable all functional diagnostics upon detection of halting debug requests. Core compare error will not be generated and flags will not update. A CPU reset is needed to ensure the CPUs are again in lockstep and will also re-enable the CCM-R5F.

13.3 Control Registers

Table 13-7 lists the CCM-R5F registers. Each register begins on a 32-bit word boundary. The registers support 32-bit, 16-bit, and 8-bit accesses. The base address for the control registers is FFFF F600h.

Table 13-7. Control Registers

Offset	Acronym	Register Description	Section

14.1 Introduction

The oscillator macro will pass a signal driven into the OSCIN pin to clock source 0 that is the device default clock source on reset. When a crystal or resonator with appropriate load circuitry is connected to OSCIN and OSCOUT, the oscillator macro drives the crystal/resonator to generate the input waveform. In addition to being directly usable as clock source 0, the oscillator clock is the input to the PLL.

The oscillator frequency is continuously monitored by a dedicated clock detect circuit. If the frequency falls out of a fixed range, the clock detect switches the clock from the oscillator to an internally generated, free-running frequency (generated by the low power oscillator (LPO)).

The phase lock loop (PLL), a circuit in the microcontroller, is used to multiply the input frequency to some higher (device operation) frequency. This frequency synthesis is useful for generating higher frequencies than can be conveniently achieved with an external crystal or resonator. Additionally, the PLL allows the flexibility to be able to synthesize one of multiple frequency options from a given crystal or resonator.

Frequency modulation can be superimposed on the synthesized frequency. The modulation provides a means to reduce the impact of electromagnetic radiation from the device; this reduction in measured radiation can be useful in sensitive applications.

14.1.1 Features

The main features of the source clock path are:

- The oscillator may drive a crystal/resonator or be driven from an external source
- The clock detect provides continuous monitoring of the oscillator frequency and provides an automatic switch over to a free-running clock in case of oscillator failure.
- The FM-PLL module can be operated in either modulation or non-modulation mode.
- The phase-frequency detector assures lock to the fundamental reference frequency.
- $$f_{PLL} = \frac{f_{OSCIN}}{NR} \times \frac{NF}{OD \times R} \quad (1)$$
  - Configurable prescale divider (NR) for the input clock
  - Configurable multiplier (NF)
  - Configurable postscale dividers (OD, R)
- The PLL may be used with modulation enabled.
  - Configurable modulation frequency (NS)
  - Configurable modulation depth (NV)
- The slip control circuitry provides flexible response to a PLL failure (slip) including reset or automatic switch over to oscillator.

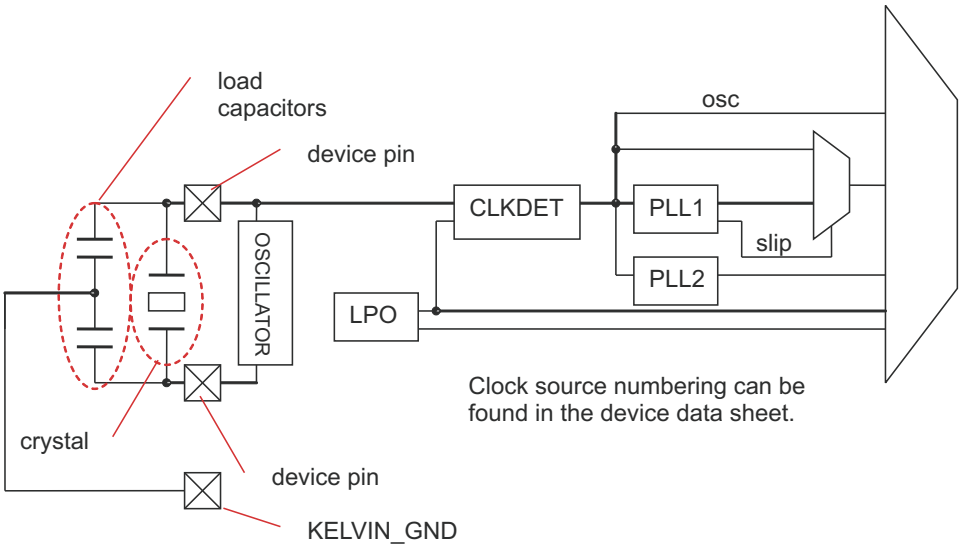
14.2 Quick Start

The purpose of this section is to provide an overview of how to configure the oscillator and PLL clock paths on power-up. More detailed descriptions are presented in later sections. Figure 14-1 shows the oscillator and PLL clock paths.



While power-on reset is asserted (low), the oscillator and low power oscillator (LPO) are enabled and start-up by default. After power-on reset is released to a high level, the clock detect circuit (CLKDET) begins to monitor the oscillator. If the oscillator is within a valid range, the oscillator becomes the default clock for the device as it exits reset; if the oscillator is not within a valid range, the clock detect selects the high-frequency low power oscillator as the default clock for the device.

The low power oscillator has a wide frequency range which also creates a large valid window for the clock detect; in order to refine the clock detect window, the low power oscillator can be trimmed. The initial trim value is stored in one-time programmable section of the flash memory, address 0xF008_01B4. Bits 31:16 of this word contain a 16 bit value that may be programmed into LPOMONCTL(15:0) in order to initialize the trim for both HF LPO and LF LPO. Software should read the initial trim values from flash and write them to the control register.

The PLL is disabled by default on power-up. The PLL control registers (PLLCTL1 and PLLCTL2) must be configured to set the desired output frequency. Then, the system PLL may be enabled (CSDISCLR.1). Similarly, the second PLL must be configured in PLLCTL3 and enabled (CSDISCLR.6). Each PLL has a valid bit that indicates the PLL is locked (CLKSRnV bit in the Clock Source Valid Status Register (CSVSTAT) of the System and Peripheral Control Registers).

Prior to selecting the PLL clock as the source for a clock domain (GCLK1, HCLK, VCLKA1), the domain and modules on the domain must be configured to accept the new frequency. An example of a module that should be configured prior to selecting the PLL as clock source for GCLK1 and HCLK is the memory wrapper to insure that access times are maintained correctly.

Figure 14-1. Clock Path from Oscillator through PLL to Device

14.3 Oscillator

The clock generation path through the PLL begins with the oscillator. The oscillator consists of three separate pads -- OSCIN, OSCOUT, and Kelvin_GND (see Figure 14-2).

The oscillator is responsible for two independent functions:

1. The oscillator is responsible for generating positive feedback in the external crystal/resonator with appropriate load and tank circuitry. At start-up, the oscillator amplifies random noise. The external circuitry acts like a band-pass and selects the crystal/resonator frequency to provide as positive feedback into the amplifier. The positive feedback increases the amplitude of the output waveform into the crystal/resonator (and the load circuitry), and the voltage waveform shows an envelope of increasing amplitude. The oscillator can drive a crystal frequency that is within the data sheet range $t_{c(OSC)}$.

   Looking at the input waveform into OSCIN, the voltage waveform is an AC-coupled, filtered version of the OSCOUT waveform. The band-pass functionality of the crystal/resonator removes distortion from the OSCOUT waveform, leaving a sinusoidal input waveform.

   NOTE: Vendor Validation of Resonators/Crystals

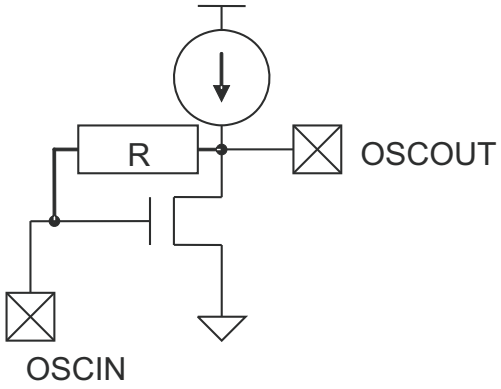
   The crystal is a very tight bandpass filter while a resonator is a somewhat wider bandpass. The load circuitry pulls the center frequency of the bandpass.

   Texas Instruments strongly encourages each customer to submit samples of the device to the resonator/crystal vendor for validation. The vendor is equipped to determine what load capacitances will best tune their resonator/crystal to the microcontroller device for optimum start-up and operation over temperature and voltage extremes. The vendor also factors in margins for variations in the microcontroller process.

2. The oscillator is also responsible for squaring-up the input waveform. This squaring-up converts the sinusoid into a square wave at the core logic levels. The input path limits the input frequency range as a low-pass filter with a cutoff frequency.

   The oscillator has a frequency range that is determined by the driving capability of external crystals/resonators (feedback path). If a clock is driven directly into the oscillator, then the feedback path is not relevant and the frequency range is determined solely by the forward path (which typically allows a higher frequency); the device can support inputs within the data sheet range $t_{c(OSC\_Sqr)}$.

Figure 14-2. Clock Generation Path



Copyright © 2018, Texas Instruments Incorporated

14.3.1 Oscillator Implementation

The oscillator operates at 3.3V and uses a constant current source to drive current onto the OSCOUT node. An internal transistor shunts the current (and current from the external circuitry) to GND. This current steering drives the voltage waveform on OSCOUT.

Figure 14-3. Oscillator Implementation

14.3.2 Oscillator Enable

The oscillator is enabled asynchronously when nPORRST is low.

The oscillator is enabled by clearing bit 0 in the Clock Source Disable Register (CSDIS) or setting bit 0 in the Clock Source Disable Clear Register (CSDISCLR) of the System and Peripheral Control Registers. The bit sends a start signal to the oscillator. Bit 0 of CSDIS is cleared to 0 by default on a system or power-on reset so that the oscillator starts-up by default. After the oscillator swings at a high-enough amplitude to pass an input clock into the core domain and nPORRST is released, 1024 oscillator periods are counted before setting the CLKSR0V bit in the Clock Source Valid Status Register (CSVSTAT) of the System and Peripheral Control Registers. The oscillator generates clock source 0 in the global clock module (GCM).

14.3.3 Oscillator Disable

The clock sources (for example, OSC, PLL) are disabled by setting the appropriate bit in the Clock Source Disable Register (CSDIS) or setting the appropriate bit in the Clock Source Disable Set Register (CSDISSET) of the System and Peripheral Control Registers. These bits *allow* the clock source to disable but do not force the behavior until the clock is no longer used as the source for a clock domain (for example, GCLK1, VCLK, VCLK2, RTICLK1). The CLKSR0V bit in the Clock Source Valid Status Register (CSVSTAT), of the System and Peripheral Control Registers, is cleared after clock disable is asserted (which occurs after all clock domains are stopped).

The oscillator disable signal places the oscillator into a low-power state, disconnects the feedback (bias) resistor between OSCIN and OSCOUT, and OSCIN is grounded.

Copyright © 2018, Texas Instruments Incorporated

14.4 Low Power Oscillator and Clock Detect (LPOCLKDET)

The Low Power Oscillator (LPO) is comprised of two oscillators -- HF LPO and LF LPO -- in a single macro. The low power oscillator and clock detect (LPOCLKDET) uses a relaxation oscillator to generate an internal clock whose frequency is NOT tightly controlled. This frequency is used to monitor the oscillator input frequency and is also available as an independent clock source in the GCM.

The LPO produces two frequencies:

- High-frequency low-power oscillator (HF LPO) with a nominal frequency of 9.6MHz and a range from 5.5MHz to 19.5MHz; the HF LPO generates clock source 5 in the GCM.
- Low-frequency low-power oscillator (LF LPO) with a nominal frequency of 85kHz; the LF LPO generates clock source 4 in the GCM.

A single current source drives current onto a capacitor; when the voltage on the capacitor exceeds some threshold, the clock toggles. The LPO uses a single current source and the two different comparators to generate the HF LPO and LF LPO frequencies. The LPO is controlled by 4 different bit fields -- CSDIS.(5:4), HFTRIM(4:0), LFTRIM(4:0), and BIASEN.

- CSDIS.5 enables/disables the comparator that generates HF LPO.
- CSDIS.4 enables/disables the comparator that generates LF LPO.
- The HF TRIM and LF TRIM bit fields vary the current into the comparator to independently trim the HF LPO and LF LPO frequencies.
- BIAS ENABLE (LPOMONCTL.24) enables/disables the current source which drives the LPO.

14.4.1 Clock Detect

The LPO HF clock frequency is typically near 9.6MHz, but ranges from 5.5MHz to 19.5MHz. The clock detect establishes a window for the oscillator by:

OSCIN > HF LPO_{min} / 4	OSCIN / 4 < HF LPO_{max}
OSCIN > 5.5[MHz] / 4 = 1.375[MHz]	OSCIN < 4 × 19.5 = 78[MHz]

The clock detect circuit works by checking for a rising edge on one clock (oscillator or HF LPO) between rising edges of the other clock. The result is that in addition to flagging incorrect, repeating frequencies, the circuit also fails due to transient conditions.

The low end of the clock detect window ignores a transient low phase of at least 12 HF LPO cycles.

NOTE: Clock Detection of Oscillator MUST be Disabled Before Disabling HF LPO

The HF LPO frequency is the comparison frequency for the oscillator. The clock detection must be disabled prior to disabling the HF LPO frequency.

If the clock detection is NOT disabled prior to disabling the HF LPO, the clock detect circuitry will fail the oscillator as too fast (compared to the non-existent HF LPO). The clock detect circuitry will switch to the non-existent clock, leaving the device without a valid clock.

14.4.2 Behavior on Oscillator Failure

If the oscillator frequency fails, the clock detects supplies:

- the HF LPO clock to GCM clock source 0 instead of the oscillator
- the HF LPO clock to GCM clock source 1 instead of the PLL

The HF LPO signal will be available as three different clock sources:

- GCM clock source 0 (replacing the oscillator)
- GCM clock source 1 (replacing the PLL)
- GCM clock source 5 as HF LPO

Copyright © 2018, Texas Instruments Incorporated

The automatic switch-over from oscillator to HF LPO allows the application to execute at a reduced frequency and respond to a problem with the external crystal/resonator. During and after an oscillator failure, the oscillator CLKSRnV bit in the Clock Source Valid Status Register (CSVSTAT), of the System and Peripheral Control Registers, is set along with the OSCFAIL flag in the Global Status Register (GLBSTAT), of the System and Peripheral Control Registers.

It is useful to explicitly change the GHVSRC register, defining the current clock source for GCLK1/HCLK/VCLK domains, to the HF LPO after an oscillator failure.

When reset on oscillator failure is set, PLLCTL1.23 (ROF), the device responds to an oscillator failure by generating a device reset.

14.4.3 Recovery from Oscillator Failure

If the oscillator fails, the clock detect switches the HF LPO frequency onto the oscillator source into the GCM. The OSCFAIL flag in the Global Status Register (GLBSTAT) of the System and Peripheral Control Registers is also set.

The oscillator may be re-enabled (though if the failure was caused by a hard-fault, the re-enable will fail) through the following procedure:

1. Switch all clock domains from the oscillator to the HF LPO (for example, GHVSRC uses HF LPO, VCLKAn uses HF LPO or VCLK, and so on).
2. If the PLL is used, disable the PLL by setting the appropriate bit in the Clock Source Disable Set Register (CSDISSET) of the System and Peripheral Control Registers.
3. Disable the oscillator by setting the appropriate bit in the Clock Source Disable Set Register (CSDISSET). This action resets the clock detect and allows the oscillator to propagate through GCM clock source 0.
4. Re-enable the oscillator by setting the appropriate bit in the Clock Source Disable Clear Register (CSDISCLR) of the System and Peripheral Control Registers.
5. Clear the OSCFAIL flag in the Global Status Register (GLBSTAT) by writing a 1 to the bit. The PLL slip bits may also be set on an oscillator failure. These can also be cleared.
6. Switch the clock domains back to the oscillator.
7. Re-enable the PLL by setting the appropriate bit in the Clock Source Disable Clear Register (CSDISCLR).

NOTE: Clock Re-Enable Procedure Will Fail If Caused by a Hard Failure

Although it is possible to re-enable the oscillator after a failure, if the oscillator failure was caused by a hard fault (for example, disconnected crystal/resonator terminal), the re-enable process will fail.

14.4.4 LPOCLKDET Enable

The LPO is enabled by default while nPORRST is low. During this time, the current source initializes, holding the relaxation oscillator in reset until initialized. After the current source releases the HF LPO and the LF LPO, these clock frequencies slew to their final frequencies; the final frequency may be achieved while nPORRST is active or after its release. After, nPORRST is released, the HF LPO Valid signal is set 32 HF LPO clock cycles later.

The clock detect is enabled once the oscillator and HF LPO are valid. Because an oscillator failure could occur from reset, the clock detect logic must provide an override path. If the HF LPO is valid and the oscillator is not valid, the clock detect circuitry will become active (overriding the oscillator invalid signal) after 16K LF LPO cycles (about 200 ms).

Copyright © 2018, Texas Instruments Incorporated

14.4.5 LPOCLKDET Disable

14.4.5.1 Disable Clock Detect

It is possible to disable the clock detect circuitry. For protection, this clock detect disable employs a 2-bit key:

- RANGE DET ENA SSET (CLKTEST.24) must be set to 1
- RANGE DET CTRL (CLKTEST.25) must be cleared to 0

In this case, the LPO HF and LF clocks are still active but the clock detect circuitry is disabled. The clock detect unconditionally switches GCM_CLK_SRC(0) back to the oscillator so care should be taken to insure that the oscillator is good before disabling the clock detect circuitry.

14.4.5.2 Disable LPO HF and LF Clocks

The LPO may be disabled by holding the relaxation oscillator clocks (HF and LF) in reset. The clock detect must be disabled, and any clock domains using either HF or LF clocks must be switched to a different clock source. The LPO HF clock is reset by setting CSDIS.5; CSDISSET.5 is an easy way to set specific bits without disturbing the rest of the register. The HF LPO clock disables several HF LPO cycles after CSDIS is set.

Similarly, the LPO LF clock is reset by setting CSDIS.4, and in a similar way CSDISSET.4 can set the specific CSDIS register bit without using a read-modify-write construction. The LF LPO disables several LF LPO cycles after CSDIS is set.

Restarting the LPO clocks from this condition is fast and is known as a warm re-start. The CSDISCLR register allows the user to clear CSDIS bits without using a read-modify-write code-construct.

14.4.5.3 Disable LPO Current Bias

The LPO current source may be disabled after the clock detect is disabled and HF and LF clock sources are disabled. Turning off this current source places the LPOCLKDET into its lowest power configuration. The bias may be disabled by clearing the BIAS ENABLE bit (LPOMONCTL.24).

Restarting the LPO when the bias current has been disabled requires the current source to initialize first and is, therefore slower than a warm re-start; re-enabling the LPO from this condition is known as a warm re-start (similar to what happens during nPORRST active).

14.4.6 Trimming the HF LPO Oscillator

The HF LPO range varies considerably around 9.6MHz from device to device. In order to provide tighter monitoring of the crystal/resonator, it is useful to trim the oscillator. During device test, a trim value is written into the one-time programmable section of the flash memory (OTP), address 0xF008_01B4. Bits 31:16 of this OTP word contain a 16 bit value that may be programmed into LPOMONCTL(15:0) in order to initialize the trim for both HF LPO and LF LPO.

When trimming the HF LPO, it is recommended to step the trim value so as not to make a large change to any TRIM setting.

After the initial trim, further trimming may be done in LPOMONCTL, using the dual clock compare module (DCC, please see Dual Clock Compare User's Guide) in order to determine the resultant frequency. This module allows for comparison of two clock frequencies. Once the HF LPO is determined to be in-range with the initial HFTRIM setting from the OTP, the crystal oscillator may be used as a reference against which the HF LPO and LF LPO may be further adjusted.

Copyright © 2018, Texas Instruments Incorporated

14.5 PLL

The following bit fields from PLLCTL1 and PLLCTL2 configure the PLL:

- REFCLKDIV[5:0]
- PLLMUL[15:0]
- ODPLL[2:0]
- PLLDIV[4:0]
- SPR_AMOUNT[8:0]
- SPREADINGRATE[8:0]
- FMENA

The PLL is responsible for synthesizing an output frequency from the input clock (from the oscillator); Figure 14-4 shows a simple block diagram of the PLL. The FM-PLL divides the reference input for a lower frequency input into the PLL ($f_{INTCLK} = f_{CLKIN}/NR$). The PLL multiplies this internal frequency by NF to get the VCO output clock frequency ($f_{Output\ CLK} = f_{INTCLK} \times NF$). The PLL output is subsequently divided by two prescale values (OD and R). The value of OD is an integer from 1-8 and R is an integer from 1 to 32. This output clock, PLL CLK, sources GCM clock source 1. Valid frequencies are shown in Table 14-1 while Table 14-2 shows how that encoding is generated from the PLL bit fields.

[$f_{(post\_ODCLK)}$ and $f_{(GCLK)}$ are data sheet parameters.]

Figure 14-4. Operation of the FM-PLL Module

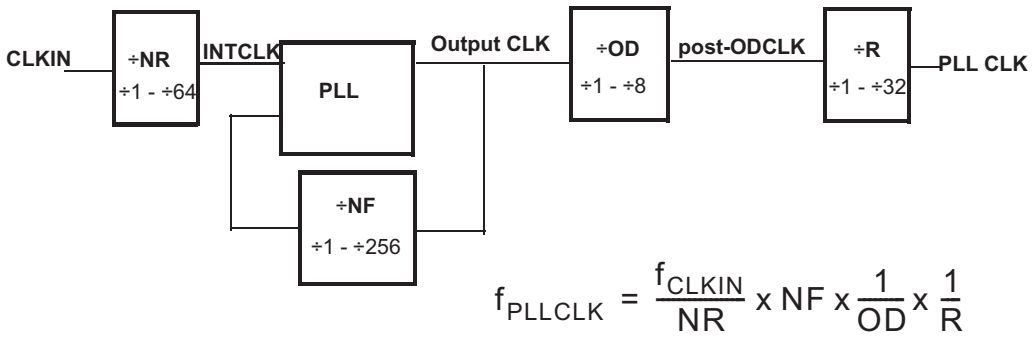


Table 14-1. Valid Frequency Ranges for PLL

	Frequency Limit
f_{CLKIN}	$f_{(OSC\_Sqr)}$
f_{INTCLK}	1MHz - $f_{(OSC\_Sqr)}$
$f_{Output\ CLK}$	150MHz - 550MHz
$f_{post\text{-}ODCLK}$	$f_{(post\_ODCLK)}$
$f_{PLL\ CLK}$	$f_{(GCLK)}$

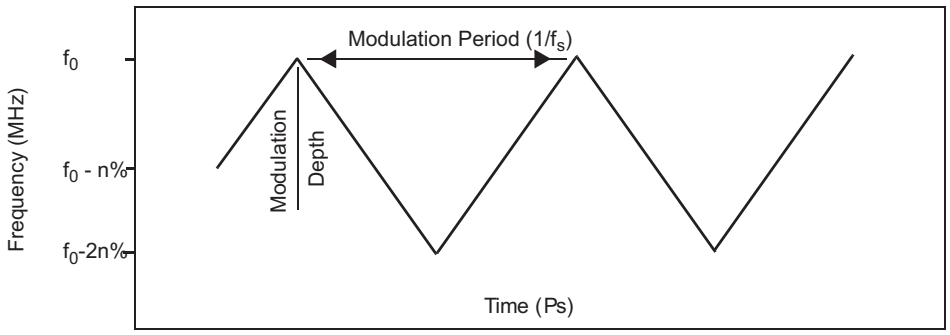
Table 14-2. PLL Value Encoding

	PLL
NR	$NR = REFCLKDIV[5...0]+1$ (2)
NF	Non-modulated: $NF = \frac{(PLLMUL[15...0] + 256)}{256}$ (3) Modulated: $NF = \frac{(PLLMUL[15...0] + MULMOD[8...0] + 256)}{256}$ (4)
NV	$NV = \frac{(SPR\_AMOUNT[8...0]+1)}{2048}$ (5)
NS	$NS = SPRRATE[8...0]+1$ (6)
OD	$OD = ODPLL[2...0]+1$ (7)

NOTE: ODPLL change should occur prior to enabling asynchronous clock domains

Since changing the ODPLL bit-field causes the PLL CLK to be gated, these changes to ODPLL should be completed before configuring a clock domain for an asynchronous clock source. Some clock domains (RTICLK1, VCLK2) require a frequency relationship to the VCLK.

$$f_{VCLK} \geq 3 \times \frac{f_{RTISRC}}{RTIDIV}$$



If the PLL is clocking VCLK and it is stopped for some cycles, then the frequency relationship is temporarily violated.

Many asynchronous domains require frequency relationships between VCLK and the asynchronous domain. Therefore, if the PLL clock is the source for GCLK1, HCLK, and VCLK, then the gating produces a short-term change in the PLL clock frequency (and hence also the VCLK frequency). As such, this frequency change could violate the requirements for an asynchronous clock domain.

14.5.1 Modulation

Optionally, the frequency can be modulated, that is, a controlled jitter is introduced onto the baseline frequency of the PLL. This modulation mechanism is not shown in Figure 14-4. When the PLL is used in the modulating mode, the programmable modulation block varies the PLL frequency from the baseline frequency ($f_{baseline}$ = (f_{CLKIN}/NR) × NF/(OD × R)) to $f_{baseline}$ × (1 - 2 × Depth) in a period defined by 1/f_s; the modulation waveform is triangular and should be enabled after lock.

The modulation is digital and the spreading profile is triangular, down-spread which implies:

- the modulation waveform is composed of a series of frequency steps.
- the modulation frequency and modulation depth are both well controlled due to their digital character.
- the average frequency during modulation is lower than the average frequency prior to enabling modulation. The depth of modulation, however, sets the new average frequency.
- the modulation frequency must be selected slower than the loop bandwidth. From a practical perspective, NS should be near 20.

The modulation fields have a simple geometric meaning:

- the modulation step size is:

$$\frac{NV}{NF} \times f_{OutputCLK} \tag{8}$$

- the number of steps per modulation period is 2 × NS
- the modulation depth is given by:

$$\Delta f = \frac{NS}{2} \times \frac{NV}{NF} \times f_{OutputCLK}$$

$$Depth[\%] = \frac{NS}{2} \times \frac{NV}{NF} \tag{9}$$

- the modulation frequency is:

$$T_{mod} = \frac{f_{OSC}}{2 \times NR \times NS} \tag{10}$$

- MULMOD minimizes frequency offset when programmed as:

$$\frac{(SPR\_AMOUNT[8...0]+1)(SPRRATE[8...0]+1)}{16} \tag{11}$$

NOTE: Modulation should be enabled after Lock

Enable modulation after the lock is completed.

14.5.2 PLL Output Control

The outputs from the PLL are the output clock, slip signals and VALID.

- RFSLIP -- the RFSLIP signal indicates that the Output CLK is running *too fast* relative to INTCLK and sets a RFSLIP status flag in the Global Status Register (GLBSTAT), of the System and Peripheral Control Registers, if the slip signal is active during normal PLL operation; the RFSLIP flag is masked off while the PLL is not active and during the PLL's lock period.
- FBSLIP -- the FBSLIP signal indicates that the Output CLK is running *too slow* relative to INTCLK and sets a FBSLIP status flag in the Global Status Register (GLBSTAT), of the System and Peripheral Control Registers, if the slip signal is active during normal PLL operation; the FBSLIP flag is masked off while the PLL is not active and during the PLL's lock period.
- PLL Slip -- Logical-OR of the two PLL slip signals. Typically this signal is used to generate a consolidated slip signal to the device (for example, error logic or exception generation). Also used to gate VALID.

NOTE: Clearing Slip Bits

In order to clear any of the slip bits, it is necessary to disable the PLL first.

- VALID -- is driven based upon whether the output clock, PLL CLK, is gated or is not gated. However, the VALID signal is dependent upon the PLL Slip signals so that VALID cannot be set if either slip signal is active.
- PLL Clock -- The PLL output clock runs at the programmed frequency. When enabled, it takes some time to acquire the programmed frequency (see Section 14.5.2.1). Similarly, the disable has some timing and constraints (see Section 14.5.2.2).

14.5.2.1 PLL Enable

After setting the PLL control registers, the clock source is enabled by clearing the appropriate bit in the Clock Source Disable Register (CSDIS) or setting the appropriate bit in the Clock Source Disable Clear Register (CSDISCLR) of the System and Peripheral Control Registers. The bit sends a signal to the PLL that starts the process of enabling the PLL.

1. The PLL checks to make sure that the oscillator is ON. If not, it turns the oscillator ON.
2. The PLL begins a locking process in which the PLL slews from a starting frequency point to the programmed frequency. During this lock period, the PLL slip signals are typically active, and the PLL masks off the signals during this phase. The lock phase takes the following length of time:

Parameter	Value
Lock	$T_{Lock} = (512 \times T_{OSCIN}) + (1024 \times NR \times T_{OSCIN})$
Enable clocks after lock	$T_{Enable} = 6 \times T_{OSCIN}$

3. After the lock phase is complete (when lock counters expire), the PLL releases the slip signals to the system.
4. Then after the slip signals are released and a delay to enable the clocks, the clock is released to the system and the appropriate CLKSRnV bit for the PLL is set in the Clock Source Valid Status Register (CSVSTAT) of the System and Peripheral Control Registers.

Copyright © 2018, Texas Instruments Incorporated

14.5.2.2 PLL Disable

The clock sources (for example, OSC, PLL) are disabled by setting the appropriate bit in the Clock Source Disable Register (CSDIS) or setting the appropriate bit in the Clock Source Disable Set Register (CSDISSET) of the System and Peripheral Control Registers. These bit allow the clock to disable but do not force the behavior until the clock is no longer used as the source for a clock domain (for example, GCLK1, VCLK, VCLK2, RTICLK1).

The PLL receives a signal to disable after the clock is no longer used by any clock domain. Within the PLL, the clock is disabled and the appropriate CLKSRnV bit for the PLL in the Clock Source Valid Status Register (CSVSTAT), of the System and Peripheral Control Registers, becomes inactive. Then the PLL is placed into a low power state after the following length of time: $T_{Enable} = 150 \times T_{OSCIN}$

14.5.2.3 OD-Divider Change

The PLL gates the clock if the ODPLL bit-field is changed while the PLL is active. The output clock from the PLL is gated for 3 or 12 OSCIN clock cycles. As the post-ODCLK is gated in the low phase, the output clock to the device -- PLL CLK -- may be gated in a high or low phase though the transition is always glitchless: $T_{ODPLL} = 3 \times T_{OSCIN}$

NOTE: ODPLL change should occur prior to enabling asynchronous clock domains

Since changing the ODPLL bit-field causes the PLL CLK to be gated, these changes to ODPLL should be completed before configuring a clock domain for an asynchronous clock source. Some clock domains (RTICLK1, VCLK2) require a frequency relationship to the VCLK.

$$f_{VCLK} \geq 3 \times \frac{f_{RTISRC}}{RTIDIV}$$

If the PLL is clocking VCLK and it is stopped for some cycles, then the frequency relationship is temporarily violated.

Many asynchronous domains require frequency relationships between VCLK and the asynchronous domain. Therefore, if the PLL clock is the source for GCLK1, HCLK, and VCLK, then the gating produces a short-term change in the PLL clock frequency (and hence also the VCLK frequency). As such, this frequency change could violate the requirements for an asynchronous clock domain.

14.5.2.4 Changing the PLL Operating Point While the PLL is Active

Once the valid bit (CLKSRnV bit in the Clock Source Valid Status Register (CSVSTAT) of the System and Peripheral Control Registers) is set, software may change values to the PLL. If the change of values results in a small percentage change to the VCO frequency ($\Delta f_{OutputCLK} < 0.1 \times f_{OutputCLK}$), then these changes can be done on-the-fly. In this mode, the values are updated into the PLL synchronously, and the PLL re-locks to the new value without gating the clocks or the slip bits. If the operating point change is too large, then the slip bits will be set.

Conversely, if the changes to the VCO frequency are large, then the PLL should be disabled prior to changing the values. Typically, any change to the REFCLKDIV field or large changes to the PLLMUL field in the PLL Control Register 1 (PLLCTL1) of the System and Peripheral Control Registers requires a complete disable-and-relock strategy.

Copyright © 2018, Texas Instruments Incorporated

14.5.2.5 Summary of PLL Timings

In addition to controlling the lock period and disabling the clock during an ODPLL change, the PLL also generates reset delays. When power-on reset is released (nPORRST 0 --> 1), that release is delayed by 1024 OSCIN cycles so that it is released at the same time that the oscillator valid is asserted. The system reset release is delayed by an additional 8 oscillator clock cycles.

Table 14-3. Summary of PLL Timings

Parameter	Value
nPORRST delay	$T_{nPORRST} = 1024 \times T_{OSCIN}$
nRST delay	$T_{nRST} = 1032 \times T_{OSCIN}$
OSC valid	$T_{OSCVALID} = 1024 \times T_{OSCIN}$
Lock	$T_{Lock} = (512 \times T_{OSCIN}) + (1024 \times NR \times T_{OSCIN})$
Enable clocks after lock	$T_{Enable} = 6 \times T_{OSCIN}$
Disable clocks after lock	$T_{Enable} = 150 \times T_{OSCIN}$
Change ODPLL	$T_{ODPLL} = 3 \times T_{OSCIN}$

Copyright © 2018, Texas Instruments Incorporated

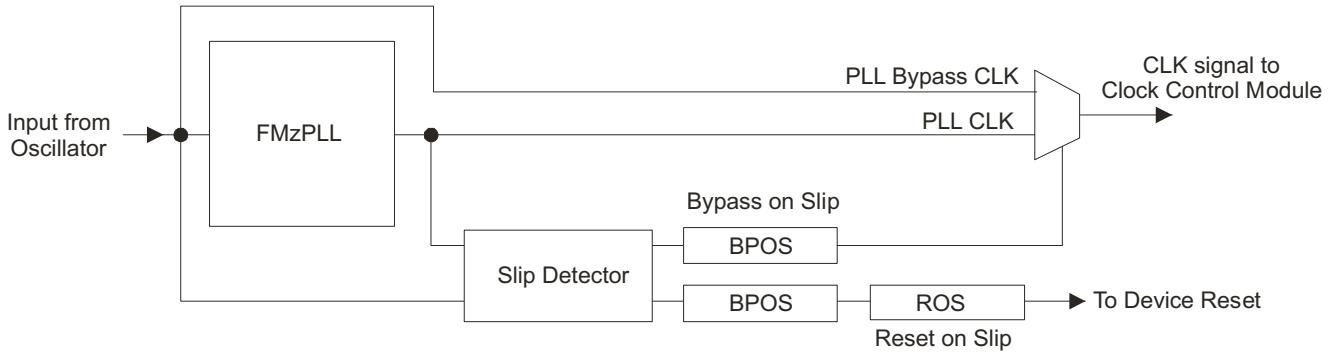
14.5.3 Behavior on PLL Fail

The PLL allows flexible response to a PLL failure (slip). Like the oscillator, the PLL clock is configured by default to automatically switch-over to the oscillator in case of a PLL slip. (In this case, the oscillator sources GCM clock source 1 as well as GCM clock source 0. Also, if the oscillator fails, LPO HF is sourced to both GCM clock sources 0 and 1.)

The PLL slip outputs indicate that the PLL is running either too fast or too slow. These error output toggle when the PLL is locking and when the PLL is disabling. The PLL blocks these slip outputs during these times, leaving them active only while the PLL is active.

A slip after the PLL has locked and while it is active is an indication of a PLL failure. The PLL provides slip-filtering which enhances the flexibility of the PLL's response to failure. The slip-filtering circuit samples the slip based on HF LPO. The filter defines the number of consecutive HF LPO cycles for which the slip signal must be active before the slip is recognized. This slip is latched in the RFSLIP and FBSLIP status flags in the Global Status Register (GLBSTAT) of the System and Peripheral Control Registers.

The PLL may enable/disable the automatic switch over as well as the error signaling; if the error signaling is enabled, a PLL slip may be configured to generate a reset. The automatic switch-over and suppression of the error signals are controlled by the bypass on slip bit field -- BPOS[1:0] (PLLCTL1.(30:29)). When BPOS[1:0] is disabled (BPOS[1:0] = 10b):



- automatic response to the PLL slip is prevented
- ESM/exception is NOT generated
- reset on slip is not generated regardless of the state of the ROS bit
- status bits are set on a PLL slip independent of BPOS[1:0]

When BPOS[1:0] is enabled (BPOS[1:0] = 00b OR 01b OR 11b):

- PLL slip causes the clock source into GCM clock source 1 to shift from the PLL to the oscillator
- ESM/exception is generated
- reset on slip is generated if ROS is set

The effect of BPOS[1:0] on the system is shown in Figure 14-5.

Figure 14-5. PLL Slip Detection and Reset/Bypass Block Diagram

14.5.4 Recovery from a PLL Failure

If PLL1 fails, the PLL's slip causes the valid flag to be locked and causes the clock source into GCM clock source 1 to shift from the PLL to the oscillator. The RFSLIP or FBSLIP status flags in the Global Status Register (GLBSTAT) of the System and Peripheral Control Registers are also set. PLL1 may be re-enabled (though if the failure was caused by a hard-fault, the re-enable will fail) through the following procedure:

1. Switch all clock domains from PLL1 to the oscillator (for example, GHVSRC uses oscillator, VCLKAn uses oscillator or VCLK, and so on).
2. Disable PLL1 by setting the appropriate bit in the Clock Source Disable Set Register (CSDISSET) of the System and Peripheral Control Registers. This action disables the PLL and causes the slip signal to no longer be driven. Valid is not released until the slip is cleared.
3. Clear the RFSLIP or FBSLIP status flags in the Global Status Register (GLBSTAT) of the System and Peripheral Control Registers by writing a 1 to the bit. After this step, the valid flag is unlocked and cleared if it was previously set.
4. Re-enable PLL1 by setting the appropriate bit in the Clock Source Disable Clear Register (CSDISCLR).
5. Switch the clock domains back to PLL1.

If PLL2 fails, the PLL's slip causes the valid flag to be locked. There is no autonomous change of clock source for PLL2. Neither the RFSLIP or FBSLIP status flags in the Global Status Register (GLBSTAT) of the System and Peripheral Control Registers are set. PLL2 may be re-enabled in a similar procedure to re-enabling PLL1 (though if the failure was caused by a hard-fault, the re-enable will fail):

1. Switch all clock domains from PLL2 to the oscillator (for example, GHVSRC uses oscillator, VCLKAn uses oscillator or VCLK, and so on).
2. Disable PLL2 by setting the appropriate bit in the Clock Source Disable Set Register (CSDISSET) of the System and Peripheral Control Registers. This action disables the PLL and causes the slip signal to no longer be driven. Valid is not released until the slip is cleared.
3. Reset PLL2 Valid by writing a 1 to both RFSLIP and FBSLIP status flags in the Global Status Register (GLBSTAT) of the System and Peripheral Control Registers (even though they are not set by the slip). After this step, the valid flag is unlocked and cleared if it was previously set.
4. Re-enable PLL2 by setting the appropriate bit in the Clock Source Disable Clear Register (CSDISCLR).
5. Switch the clock domains back to PLL2.

14.5.5 PLL Modulation Depth Measurement

The PLL contains a circuit for estimating the depth of the modulation. The circuit counts clock edges over a fixed window of the modulation waveform (SSW_CAPTURE_COUNT in SSWPLL2) and clock edges over the entire waveform (SSW_CLKOUT_COUNT in SSWPLL3). The capture ends after a pre-determined number of clock edges in SSW_CLKOUT_COUNTER as set in TAP_COUNTER_DIS. There are 2 × NR windows per modulation waveform. The procedure for estimating the modulation depth is:

1. While GCLK1 is sourced by the oscillator and the PLL is enabled with modulation, configure SSWPLL1 as follows:
   a. CAPTURE_WINDOW_INDEX is set equal to NR.
   b. COUNTER_RESET is set.
   c. TAP_COUNTER_DIS is set to disable the measurement after SSW_CLKOUT_COUNT captures this number of clocks. The measurement is disabled after the set tap is set AND the modulation cycle ends.
   d. Ensure that EXT_COUNTER_EN is cleared.
2. Ensure that both SSW_CAPTURE_COUNT and SSW_CLKOUT_COUNT are cleared (by the COUNTER_RESET).
3. Set COUNTER_EN and clear COUNTER_RESET. This step releases the reset and enables the counter to begin counting.
4. After a wait loop, poll for COUNTER_READ_READY to set. After the bit is set, read SSW_CAPTURE_COUNT and SSW_CLKOUT_COUNT.
5. Compute the modulation depth as:

$$Depth = abs\left(1 - \frac{2 \times NR \times SSW\_CAPTURE\_COUNT}{SSW\_CLKOUT\_COUNT}\right) \quad (12)$$

14.5.6 PLL Frequency Measurement Circuit

The same circuit that is used to measure modulation depth is also available to measure the average frequency of the PLL. In this mode, the PLL output (before the R-divider) is captured in SSW_CLKOUT_COUNT while the oscillator is captured in SSW_CAPTURE_COUNT. The procedure for using the PLL frequency measurement circuit is:

1. While the PLL is enabled, set EXT_COUNTER_EN.
2. Set COUNTER_EN. This bit clears both SSW_CAPTURE_COUNT and SSW_CLKOUT_COUNT and then immediately enables for counting.
3. Wait for some software delay loop.
4. Clear COUNTER_EN. Wait for COUNTER_READ_READY to set. Read both SSW_CAPTURE_COUNT and SSW_CLKOUT_COUNT and compute the ratio of PLL multiplication as:

$$\frac{NF}{NR \times OD} = \frac{SSW\_CLKOUT\_COUNT}{SSW\_CAPTURE\_COUNT} \quad (13)$$

5. Note that CAPTURE_WINDOW_INDEX, COUNTER_RESET, TAP_COUNTER_DIS are not used in this procedure

14.5.7 PLL2

PLL2 drives GCM clock source 6.

The PLL is identical to PLL1, except modulation is disabled on this instance of the PLL. Also, the PLL typically does not clock the system, there is no automatic switch over feature. Any PLL error can be handled by the CPU.

PLL2 is programmed through PLLCTL3.

14.6 PLL Control Registers

The clock module has two registers (PLLCTL1 and PLLCTL2) located within the System and Peripheral Control Registers, plus it has four bits located in other System and Peripheral Control Registers.

The FM-PLL is off at power-on. The clock source is enabled by clearing the appropriate bit in the Clock Source Disable Register (CSDIS) or setting the appropriate bit in the Clock Source Disable Clear Register (CSDISCLR) of the System and Peripheral Control Registers. [CSDISCLR and Clock Source Disable Set Register (CSDISSET) also enable/disable the PLL and oscillator (and other clock sources).]

The LPOCLKDET module generates the OSCFAIL flag in the Global Status Register (GLBSTAT), of the System and Peripheral Control Registers, if a problem with the reference oscillator is detected. The slip signals are also registered in the RFSLIP and FBSLIP status flags in the Global Status Register (GLBSTAT), of the System and Peripheral Control Registers, in order to indicate the source of a clock failure.

The appropriate CLKSRnV bit for the PLL is set in the Clock Source Valid Status Register (CSVSTAT) of the System and Peripheral Control Registers.

The following sections describe the two PLL registers used in the system module. These registers support 8-, 16-, and 32-bit write accesses. The reset values for these registers are configured so that an input frequency in the range from 5 MHz to 20 MHz generates a valid clock.

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 14-6. SSW PLL BIST Control Register 1 (SSWPLL1) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
15-8	CAPTURE_WINDOW_INDEX	0-FFh	The capture counter present in the PLL wrapper will count the PLL clock edges when the current modulation phase capture window value is equal to these bits. Should be set equal to NR.
7	Reserved	0	Reads return 0. Writes have no effect.
6	COUNTER_READ_READY		Counter read ready. Indicates that SSW_CAPTURE_COUNT (SSWPLL2) and SSW_CLKOUT_COUNT (SSWPLL3) can be read.
		0	Counter registers in SSWPLL2 and SSWPLL3 are not ready to read.
		1	Counter registers in SSWPLL2 and SSWPLL3 are ready to read.
5	COUNTER_RESET		Counter reset. If EXT_COUNTER_EN = 0, COUNTER_RESET resets SSW_CAPTURE_COUNT (SSWPLL2) and SSW_CLKOUT_COUNT (SSWPLL3). If EXT_COUNTER_EN = 1, this bit is ignored.
		0	No impact to counters.
		1	If the EXT_COUNTER_EN bit is 0, then counters SSW_CAPTURE_COUNT and SSW_CLKOUT_COUNT will be held in the reset state. If EXT_COUNTER_EN bit is 1, then this bit will be ignored by the PLL wrapper.
4	COUNTER_EN		Counter enable. If EXT_COUNTER_EN = 0, COUNTER_EN initializes the modulation depth measurement. (In this mode, the disable is set to occur automatically.) If EXT_COUNTER_EN = 1, the counters are enabled/disabled with COUNTER_EN.
		0	If EXT_COUNTER_EN = 0, COUNTER_EN = 0 indicates that the counters are inactive. If EXT_COUNTER_EN = 1, COUNTER_EN = 0 disables the counters.
		1	If EXT_COUNTER_EN = 0, COUNTER_EN = 1 indicates that the counters are still active. If EXT_COUNTER_EN = 1, COUNTER_EN = 1 enables the counters.

Table 14-6. SSW PLL BIST Control Register 1 (SSWPLL1) Field Descriptions (continued)

Bit	Field	Value	Description
3-1	TAP_COUNTER_DIS		The value in this register is used to program a particular bit in CLKOUT counter. When that particular bit in CLKOUT counter becomes 1, then both the CLKOUT counter and the CAPTURE counter will stop counting when EXT_COUNTER_EN = 0. When EXT_COUNTER_EN = 1, this bit field is not used.
		0	Bit 16 of CLKOUT counter is selected. When this bit is set and the modulation period finishes, the counters are disabled and READ_READY_FLAG is set.
		1h	Bit 18 of CLKOUT counter is selected.
		2h	Bit 20 of CLKOUT counter is selected.
		3h	Bit 22 of CLKOUT counter is selected.
		4h	Bit 24 of CLKOUT counter is selected.
		5h	Bit 26 of CLKOUT counter is selected.
		6h	Bit 28 of CLKOUT counter is selected.
		7h	Bit 30 of CLKOUT counter is selected.
0	EXT_COUNTER_EN		Measurement mode.
		0	Modulation Depth Measurement mode.
		1	Frequency Measurement mode.

14.6.2 SSW PLL BIST Control Register 2 (SSWPLL2)

This is an observation register used to log counter value for the capture counter inside the PLL wrapper. The SSWPLL2 register is shown in Figure 14-7 and described in Table 14-7. This register applies to PLL1, but does not apply to PLL2.

Figure 14-7. SSW PLL BIST Control Register 2 (SSWPLL2) [offset = 28h]

14.7 Phase-Locked Loop Theory of Operation

The PLL block consists of six logical sub-blocks:

- Phase-Frequency Detector (PFD)
- Charge Pump (CP)
- Loop Filter (LF)
- Voltage-Controlled Oscillator (VCO)
- Frequency Modulation
- Slip Detector

Figure 14-9 illustrates the sub-blocks in a basic PLL circuit. The VCO adjusts its frequency until the two signals into the PFD have the same phase and frequency. The feedback path (from VCO to PFD) divides the frequency of the feedback signal by 2 × NF; this feedback divider requires the VCO to generate a frequency 2 × NF times greater than the internal frequency (OSCIN/NR). In the forward path (from VCO to PLL CLK), the /2 block creates a clean duty cycle.

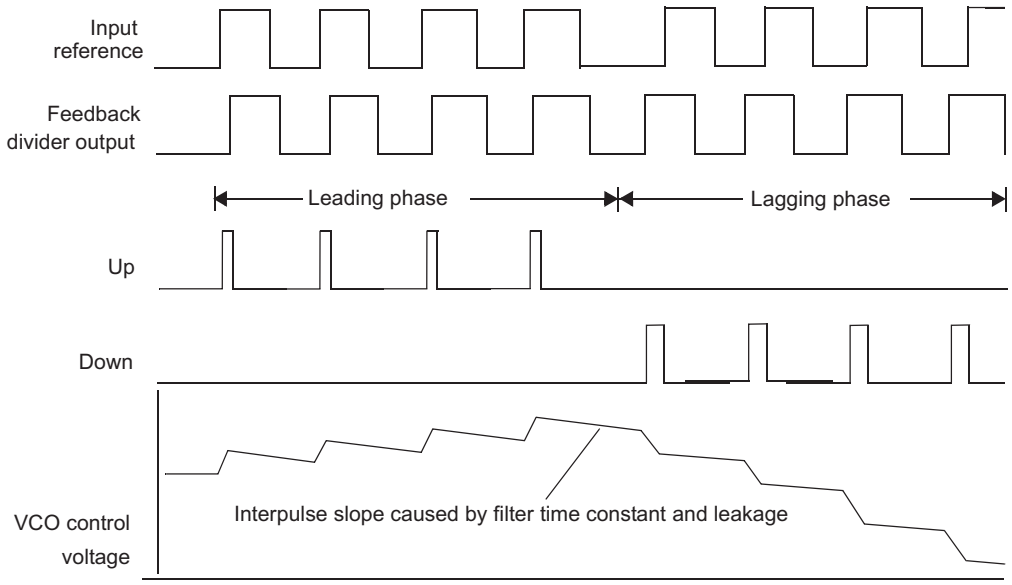

Figure 14-9. Basic PLL Circuit

14.7.1 Phase-Frequency Detector

The phase-frequency detector (PFD) compares the input reference phase/frequency to the phase/frequency of the feedback divider and generates two signals: an *up* pulse and a *down* pulse that drive a charge pump. The resulting charge, when integrated by the circuit at the LF pin, provides a VCO control voltage, as shown in Figure 14-10.

Figure 14-10. PFD Timing

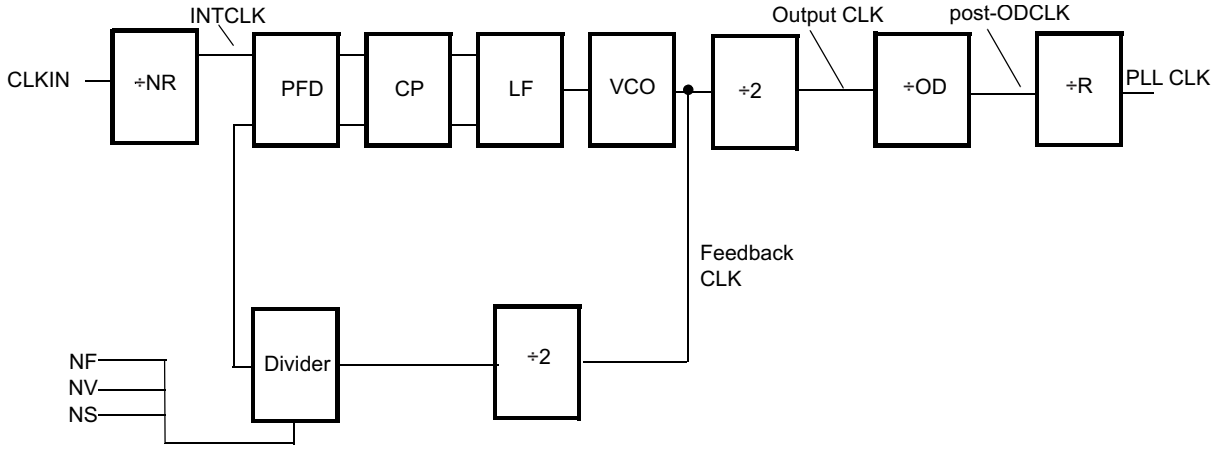
Copyright © 2018, Texas Instruments Incorporated

The width of the up pulse and the down pulse depends on the difference in phase between the two inputs. For example, when the reference input leads the feedback input by 10 ns, then an up pulse of approximately 10 ns is generated (see Figure 14-10). On the other hand, when the reference input lags the feedback input by 10 ns, then a down pulse of approximately 10 ns is generated. When the two inputs are exactly in phase, the up pulse and down pulse become essentially zero-width. These pulses are fed to the charge pump block, which meters charge into the low-pass loop filter.

The advantage of a phase-frequency detector over a phase-only detector is that it cannot lock to a harmonic or subharmonic of the reference. This important property also ensures that the output frequency of the VCO is always exactly 2 × NF times the reference frequency.

The reference feedback frequency is based upon the VCO frequency and the feedback divider. Fractional multiplication is achieved by changing the feedback divider real-time in order to create the fractional multiplication. As an example, if a multiplier of 100.5 is selected, the feedback divider divides by 100 and 101 in equal proportions; in this case, the PLLMUL bit field would be programmed as 99.5 (0x6380). This fractional multiplication is useful when trying to achieve final frequencies that are non-integer to the input frequency (a final frequency that is a prime number). The fractional portion of the divider should be small compared to the multiplier and so it is recommended that the fractional portion relate to parts in 16, implying that the last 4 bits should always be 0.

14.7.2 Charge Pump and Loop Filter



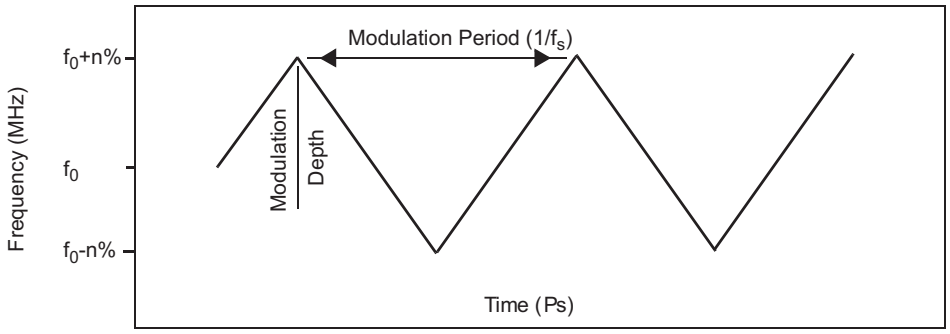
The charge pump (CP) add or remove charge from the loop filter based on the pulses coming from the phase-frequency detector (PFD).

Two components of the filter output signal are summed together: an integral component and a proportional component. The integral component maintains a DC level going to the VCO to set its frequency, and the proportional component makes the VCO track changes in phase to minimize jitter. The capacitors and resistors required for the filter are integrated in silicon.

14.7.3 Voltage-Controlled Oscillator

The output frequency of the VCO is proportional to its input control voltage, which is generated by the charge pump via the integrated loop filter. If the VCO oscillates too slowly, the feedback phase begins to lag the reference phase at the PFD, which increases the control voltage at the VCO. Conversely, if the VCO oscillates too fast, the feedback phase begins to lead the reference phase at the PFD, which decreases the control voltage at the VCO. These two actions keep the VCO running at the correct frequency multiple of the reference.

Figure 14-11. PLL Modulation Block Diagram



Copyright © 2018, Texas Instruments Incorporated

14.7.4 Frequency Modulation

The output clock of the PLL changes frequency in a controlled way, centered around the unmodulated output frequency. The modulation block directly modulates the VCO frequency at the loop filter, and creates the triangular frequency modulation (see Figure 14-12).

Figure 14-12. Frequency versus Time

14.8 Programming Example

This section provides an example of how to program the PLL. For non-modulation settings, the PLLCTL1 and PLLCTL2 settings from 130nm process devices can be used without modification.

Suppose that, using a 20 MHz crystal, the application requires:

- 180 MHz GCLK1 (and HCLK) frequency
- 100 kHz spreading frequency
- 0.5% spreading depth

1. Choose an NR and NS such that:
   - $$\frac{f_{CLKIN}}{NR \times f_s} \geq 40 \quad (14)$$
   - $$f_s \equiv \frac{f_{CLKIN}}{2 \times NR \times NS} \quad (15)$$
   - $$2 \times NS = \frac{f_{CLKIN}}{NR \times f_s} \geq 40 \quad (16)$$
   - (NR,NS) = {(5,20), (4,25), (2,50), (1,100)}
   - Either NR = 5 and NS = 20 or NR = 4 and NS = 25 are reasonable. Another choice (NR = 3 and NS = 33) is possible, if the modulation frequency can vary from 100 KHz.
2. Choose Output CLK frequency as integer divider of output frequency near to 330 MHz. Output CLK frequency shall not exceed 550 MHz or fall below 150 MHz.

   The integer values for 180 MHz are 360 MHz or 540 MHz. 360 MHz is close to the target frequency of 330 MHz and we use this frequency.
3. In this case, either of the following equations are suitable choices for getting to 360 MHz. Choose NR = 5, NS = 20 and set NF = 90 or choose NR = 4, NS = 25 and set NF = 72.

   $$\frac{f_{CLKIN}}{NR} = \frac{20[MHz]}{4} = 5[MHz] \ \ or \ \ \frac{f_{CLKIN}}{NR} = \frac{20[MHz]}{5} = 4[MHz] \quad (17)$$
4. Select the output divider OD so that the post-ODCLK frequency does not exceed the maximum frequency of output divider R (device-specific frequency). In this case, choose OD = 2 and R = 1.

Copyright © 2018, Texas Instruments Incorporated

5. Compute the divider value NV:

$$Depth = \frac{0.5}{100} = \frac{NV}{NF} \times \frac{NS}{2} = \frac{NV}{90} \times \frac{20}{2} \quad (18)$$

NV = 0.045

6. If it is important to maintain the same average frequency in modulation as in non-modulation, either NF should be modified OR program the MULMOD bit field. The modulation fields create a multiplier offset equal to:

$$\Delta NF = \frac{NV \times NS}{2} \quad (19)$$

If using MULMOD[8:0], then:

$$\Delta NF = \frac{MULMOD[8...0]}{256} = \frac{NV \times NS}{2} = \frac{0.045 \times 20}{2} \quad (20)$$

$$MULMOD[8...0] = \frac{0.045 \times 20}{2} \times 256 = 115.2 \quad (21)$$

MULMOD will be set to 115.

7. Convert the PLL parameters into bit field values:
   - NR = 5, implies that REFCLKDIV[5:0] = 4
   - NS = 20, implies that SPRATE[8:0] = 19 = 0x13
   - NF = 90, implies that PLLMUL[15:0] = 0x5900
   - OD = 2, implies that ODPLL[2:0] = 1
   - R = 1, implies that PLLDIV[4:0] = 0
   - NV = 0.045, implies that SPR_AMOUNT[8:0] = 91 = 0x5B
   - MULMOD[8:0] = 115 = 0x73
8. Setting only these fields (that is, not BPOS, ROF, or ROS) yields:

   PLLCTL1 = 0x00045900

   PLLCTL2 = 0x04C7325B

   When FM ENA is turned on, PLLCTL2 = 0x84C7325B.

   The Output CLK is centered in the range from 150 MHz to 550 MHz at 360 MHz.

   NF = 90 falls within the multiplier range from 1 to 256.

   OD is selected so that post-ODCLK meets the device specification.

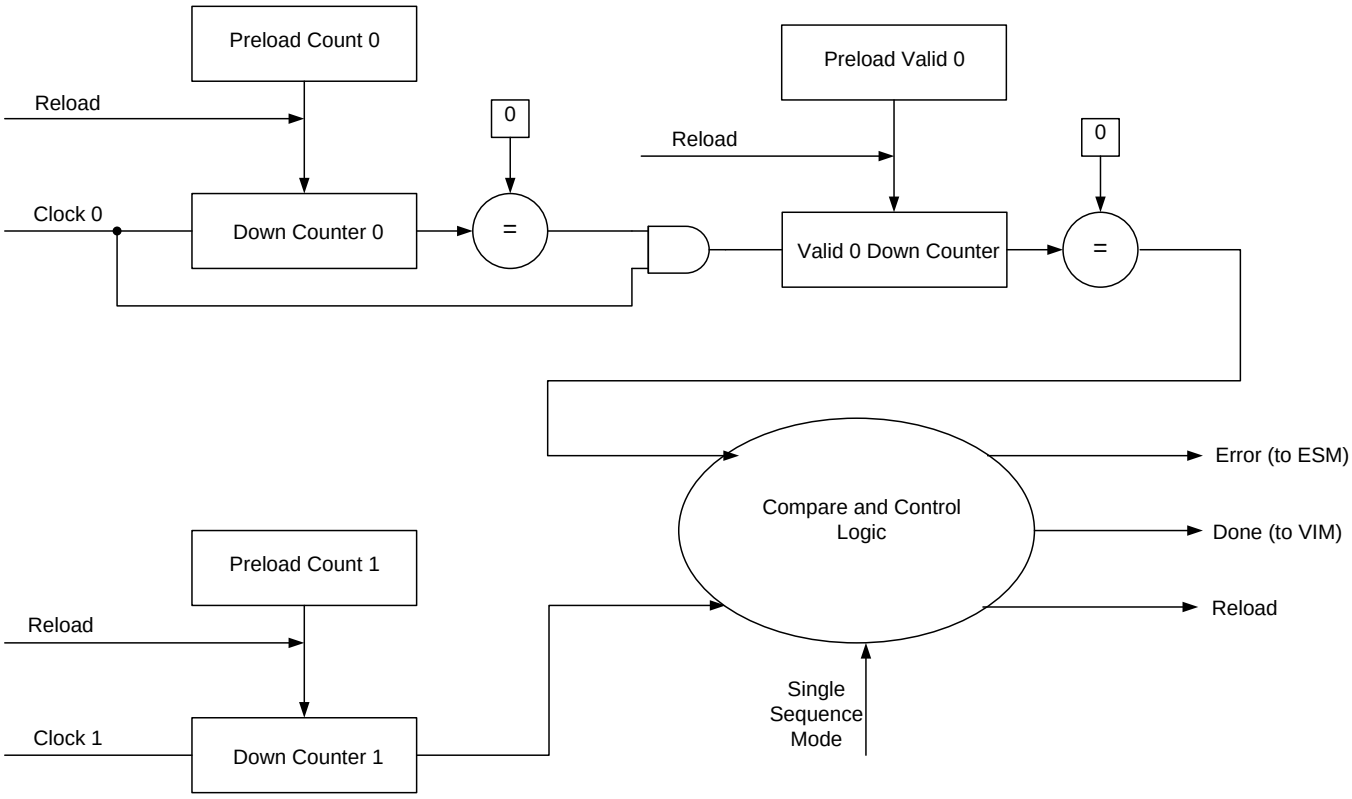
15.1 Introduction

The primary purpose of a DCC module is to measure the frequency of a clock signal using a second known clock signal as a reference. This capability can be used to ensure the correct frequency range for several different device clock sources, thereby enhancing the system safety metrics.

15.1.1 Main Features



The main features of each of the DCC modules are:

- Allows application to ensure that a fixed ratio is maintained between frequencies of two clock signals
- Supports the definition of a programmable tolerance window in terms of number of reference clock cycles
- Supports continuous monitoring without requiring application intervention
- Also supports a single-sequence mode for spot measurements
- Allows selection of clock source for each of the counters resulting in several specific use cases

15.1.2 Block Diagram

Figure 15-1 illustrates the main concept of the DCC module.

Figure 15-1. DCC Operation

Copyright © 2018, Texas Instruments Incorporated

15.2 Module Operation

As shown in Figure 15-1, the DCC contains two counters – counter0 and counter1, which are driven by two signals – clock0 and clock1. The application programs the seed values for both these counters. The application also configures the tolerance window time by configuring the valid counter for clock0.

Counter0 and counter1 both start counting simultaneously once the DCC is enabled. When counter0 counts down to zero, this automatically triggers the count down of the tolerance window counter (valid0).

The DCC module can be used in two different operating modes:

15.2.1 Continuous Monitoring Mode

In this mode, the DCC is used by the application to ensure that two clock signals maintain the correct frequency ratio. Suppose the application wants to ensure that the PLL output signal (clock source # 1) always maintains a fixed frequency relationship with the main oscillator (clock source # 0).

- In this case, the application can use the main oscillator as the clock0 signal (for counter0 and valid0) and the PLL output as the clock1 (for counter1).
- The seed values of counter0, valid0 and counter1 are selected such that if the actual frequencies of clock0 and clock1 are equal to their expected frequencies, then the counter1 will reach zero either at the same time as counter0 or during the count down of the valid0 counter.
- If the counter1 reaches zero during the count down of the valid0 counter, then all the counters (counter0, valid0, counter1) are reloaded with their initial seed values once valid0 has also counted down to zero.
- This sequence of counting down and checking then continues as long as there is no error, or until the DCC module is disabled.
- The counters also all get reloaded if the application resets and restarts the DCC module.

Error Conditions:

An error condition is generated by any one of the following:

1. Counter1 counts down to 0 before Counter0 reaches 0. This means that clock1 is faster than expected, or clock0 is slower than expected. It includes the case when clock0 is stuck at 1 or 0.
2. Counter1 does not reach 0 even when Counter0 and Valid0 have both reached 0. This means that clock1 is slower than expected. It includes the case when clock1 is stuck at 1 or 0.

   Any error freezes the counters from counting. An application may then read out the counter values to help determine what caused the error.

15.2.1.1 Error Conditions

While operating in continuous mode, the counters get reloaded with the seed values and continue counting down under the following conditions:

- The module is reset or restarted by the application, OR
- Counter0, Valid 0 and Counter1 all reach 0 without any error

15.2.2 Single-Shot Measurement Mode

The DCC module can be programmed to count down one time by enabling the single-shot mode. In this mode, the DCC stops operating when the down counter0 and the valid counter0 reach 0. Alternatively, the DCC can be programmed to stop counting when the down counter1 reaches 0.

At the end of one sequence of counting down in this single-shot mode, the DCC gets disabled automatically, which prevents further counting. This mode is typically used for spot measurements of the frequency of a signal. This frequency could be an unknown for the application before the measurement.

Example Usage of Single-Shot Measurement Mode: Trimming the High-Frequency Low-Power Oscillator

A practical example of the usage of the spot measurement mode is in trimming the HF LPO (clock source # 5) using the main oscillator as a reference. This measurement sequence would proceed as follows:

- The application sets up the seed values for counter0 and valid0 for the duration of the measurement. Suppose the main oscillator frequency is 10MHz and the intended duration of the measurement is 500µs. The application needs to configure a seed value of 5000.
- These 5000 counts need to be divided between the counter0 and the valid0 counters. The minimum value for the valid0 seed is 4, so the application can configure counter0 seed value as 4996 and the valid0 seed value as 4.
- Suppose the HF LPO frequency is truly unknown. In this case the application can choose the maximum allowed seed value for counter1. This increases the probability of counter0 and valid0 counting down while the counter1 has still not fully counted down to zero. The maximum allowed seed value for counter1 is 1048575.
- Once the DCC is enabled, the counters counter0 and counter1 both start counting down from their seed values.
- When counter0 reaches zero, it automatically triggers the valid0 counter.
- When valid0 reaches zero, if counter1 is not zero as well, an ERROR status flag is set and a "DCC error" is sent to the ESM. Counter1 is also frozen so that it stops counting down any further. The application can enable an interrupt to be generated from the ESM whenever this DCC error is indicated. Refer the device datasheet to identify the ESM group and channel where the DCC error is connected.

Copyright © 2018, Texas Instruments Incorporated

- The DCC error interrupt service routine can then check the value of counter1 when the error was generated. Suppose that the counter1 now reads 1044575. This means that counter1 has counted 1048575 - 1044575, or 4000 cycles within the 500µs measurement period. This means that the average frequency of the HF LPO over this 500µs period was 4000 cycles / 500µs, or 8MHz.
- The application then needs to clear the ERROR status flag and restart the DCC module so that it is ready for the next spot measurement.

If there is no error generated at the end of the sequence, then the DONE status flag is set and a DONE interrupt is generated. The application must clear the DONE flag before restarting the DCC.

The conditions that cause a DCC error are identical between the continuous monitoring mode and the single-shot measurement mode.

Error Conditions:

An error condition is generated by any one of the following:

1. Counter1 counts down to 0 before Counter0 reaches 0. This means that clock1 is faster than expected, or clock0 is slower than expected. It includes the case when clock0 is stuck at 1 or 0.
2. Counter1 does not reach 0 even when Counter0 and Valid0 have both reached 0. This means that clock1 is slower than expected. It includes the case when clock1 is stuck at 1 or 0.

   Any error freezes the counters from counting. An application may then read out the counter values to help determine what caused the error.

Freezing Counters when Counter1 Reaches Zero:

The DCC module also allows the counters to be frozen when the counter1 reaches zero. This allows one of the clock sources for counter1 to be used as a reference for measuring one of the clock sources for counter0. The error conditions are the same as those where (counter0=0 and valid0=0) define the condition when the DCC counters are frozen. That is, an error is indicated if coutner0 and valid0 become zero while counter1 is still non-zero. In this case, however, the application would typically set up the seed values such that the counter1 will become zero before counter0. Essentially the measurement period is defined by the seed value of the counter1. Note that this is also an error condition, and the interrupt service routine can use the measurement period and the actual cycles counted by counter1 to determine the frequency of the clock0 signal.

15.3 Clock Source Selection for Counter0 and Counter1

Refer to the device datasheet to identify the available options for selecting the clock sources for both counters of the DCC module. Some microcontrollers may include multiple instances of the DCC module. This will also be identified in the device datasheet.

The selection of the clock sources for counter0 and coutner1 is done by a combination of the KEY, CNT0 CLKSRC, and CNT1 CLKSRC control fields of the CNT0CLKSRC and CNT1CLKSRC registers.

15.4 DCC Control Registers

This section describes the dual-clock comparator (DCC) module control and status registers. The registers support 8-bit, 16-bit or 32-bit writes and are aligned on a word (32-bit) boundary. Table 15-1 shows address offsets from the module base address. The base address for the control registers is FFFF EC00h for DCC1 and FFFF F400h for DCC2.

Table 15-1. DCC Control Registers

Error Signaling Module (ESM)

This chapter provides the details of the error signaling module (ESM) that aggregates device errors and provides internal and external error response based on error severity.

Topic **Page**

16.1 Overview 559
16.2 Module Operation 561
16.3 Recommended Programming Procedure 564
16.4 ESM Control Registers 565

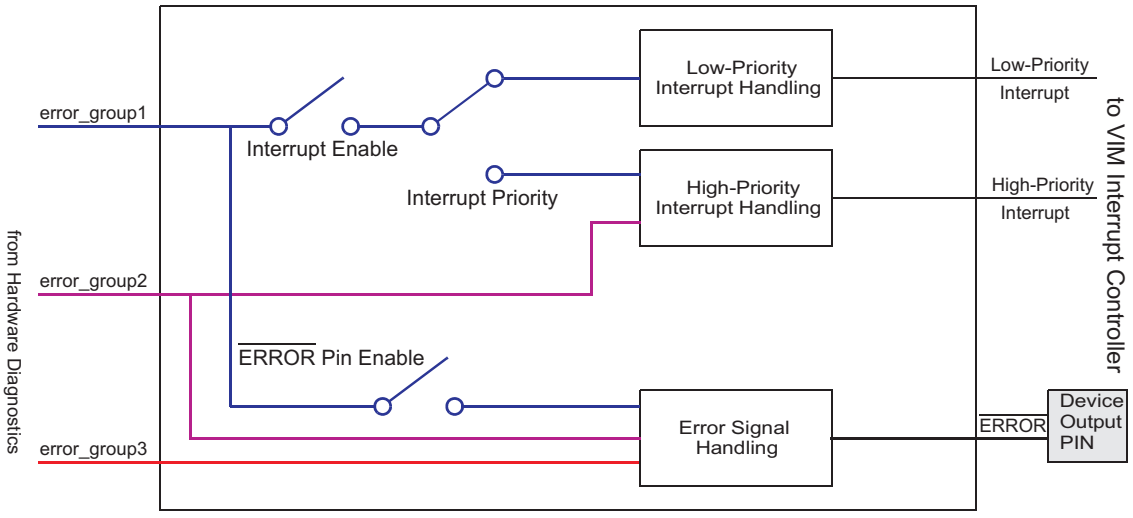
16.1 Overview

The Error Signaling Module (ESM) collects and reports the various error conditions on the microcontroller. The error condition is categorized based on a severity level. Error response is then generated based on the category of the error. Possible error responses include a low priority interrupt, high priority interrupt, and an external pin action.

16.1.1 Feature List



- Up to 160 error channels are supported, divided into 3 different groups:
  - 96 Group1 (low severity) channels with configurable interrupt generation and configurable $\overline{\text{ERROR}}$ pin behavior
  - 32 Group2 (high severity) channels with predefined interrupt generation and predefined $\overline{\text{ERROR}}$ pin behavior
  - 32 Group3 (high severity) channels with no interrupt generation and predefined $\overline{\text{ERROR}}$ pin behavior. These channels have no interrupt response as they are reserved for CPU based diagnostics that generate aborts directly to the CPU.
- Dedicated device $\overline{\text{ERROR}}$ pin to signal an external observer
- Configurable timebase for $\overline{\text{ERROR}}$ pin output
- Error forcing capability for latent fault testing

16.1.2 Block Diagram

As shown in Figure 16-1, the ESM channels are divided into three groups. Group1 channels are considered to be low severity. Group1 errors have a configurable interrupt response and configurable $\overline{\text{ERROR}}$ pin behavior. Note that the ESM Status Register 1 (ESMSR1) for error group 1 gets updated, regardless if the interrupt enable is active or not. Group2 channels are $\overline{\text{ERROR}}$ high severity. Group2 errors always generate a high priority interrupt and an output on the $\overline{\text{ERROR}}$ pin. Group3 channels indicate errors of the highest severity. Check the specific part's datasheet for identifying group3 errors and their expected responses. Group3 errors always generate an $\overline{\text{ERROR}}$ pin output.

The ESM interrupt and $\overline{\text{ERROR}}$ pin behavior are also summarized in Table 16-1.

Figure 16-1. Block Diagram

Note that the ESM Status Register 1 (ESMSR1) for error_group1 gets updated, regardless if the interrupt enable is active or not.

Table 16-1. ESM Interrupt and $\overline{\text{ERROR}}$ Pin Behavior

Error Group	Interrupt Generated	Interrupt Priority	$\overline{\text{ERROR}}$ Pin Response Generated
1	configurable interrupt	configurable priority	configurable output generation
2	interrupt generated	high priority	output generated
3	no interrupt	NA	output generated

Figure 16-2 and Figure 16-3 show the interrupt response handling and $\overline{\text{ERROR}}$ pin response handling with register configuration. The total active time of the $\overline{\text{ERROR}}$ pin is controlled by the Low-Time Counter Preload register (LTCP) and the key register (ESMEPSR) as shown in Figure 16-3. See Section 16.2.2 for details.

16.2 Module Operation

This device has 160 error channels, divided into 3 different error groups. Please refer to the device datasheet for ESM channel assignment details.

The ESM module has error flags for each error channel. The error status registers ESMSR1, ESMSR4, ESMSR7, ESMSR2, ESMSR3 provide status information on a pending error of Group1 (Channel 0-31), Group1 (Channel 32-63), Group1 (Channel 64-95), Group2, and Group3, respectively. The ESMEPSR register provides the current $\overline{\text{ERROR}}$ status. The module also provides a status shadow register, ESMSSR2, which maintains the error flags of Group2 until power-on reset ($\overline{\text{PORRST}}$) is asserted. See Section 16.2.1 for details of their behavior during power on reset and warm reset.

Once an error occurs, the ESM module will set the corresponding error flags. In addition, it can trigger an interrupt, $\overline{\text{ERROR}}$ pin outputs low depending on the ESM settings. Once the $\overline{\text{ERROR}}$ pin outputs low, a power on reset or a write of 0x5 to ESMEKR is required to release the ESM error pin back to normal state. See Section 16.2.2 for details. The application can read the error status registers (ESMSR1, ESMSR4, ESMSR7, ESMSR2, and ESMSR3) to debug the error. If an $\overline{\text{RST}}$ is triggered or the error interrupt has been served, the error flag of Group2 should be read from ESMSSR2 because the error flag in ESMSR2 will be cleared by $\overline{\text{RST}}$.

You can also test the functionality of the $\overline{\text{ERROR}}$ pin by forcing an error. See Section 16.2.3 for details.

16.2.1 Reset Behavior

Power on reset:

- $\overline{\text{ERROR}}$ pin behavior

  When nPORRST is active, the $\overline{\text{ERROR}}$ pin is in a high impedance state (output drivers disabled).
- Register behavior

  After $\overline{\text{PORRST}}$, all registers in ESM module will be re-initialized to the default value. All the error status registers are cleared to zero.

Warm reset ($\overline{\text{RST}}$):

- $\overline{\text{ERROR}}$ pin behavior

  During $\overline{\text{RST}}$, the $\overline{\text{ERROR}}$ pin is in “output active” state with pull-down disabled. The $\overline{\text{ERROR}}$ pin remains unchanged after $\overline{\text{RST}}$.
- Register behavior

  After $\overline{\text{RST}}$, ESMSR1, ESMSR4, ESMSR7, ESMSSR2, ESMSR3 and ESMEPSR register values remains un-changed. Since $\overline{\text{RST}}$ does not clear the critical failure registers, the user can read those registers to debug the failures after $\overline{\text{RST}}$ pin goes back to high.

  After $\overline{\text{RST}}$, if one of the flags in ESMSR1, ESMSR4 and ESMSR7 is set, the interrupt service routine will be called once the corresponding interrupt is enabled.

NOTE: ESMSR2 is cleared after $\overline{\text{RST}}$. The flag in ESMSR2 gets cleared when reading the appropriate vector in the ESMIOFFHR offset register. Reading ESMIOFFHR will not clear the ESMSR1, ESMSR4, ESMSR7 and the shadow register ESMSSR2. Reading ESMIOFFLR will also not clear the ESMSR1, ESMSR4 and ESMSR7.

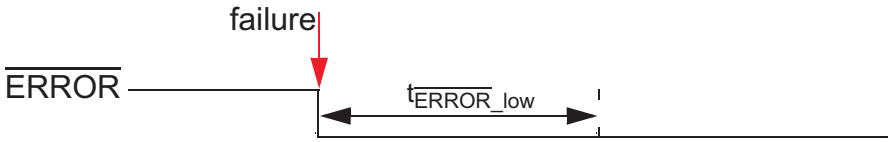
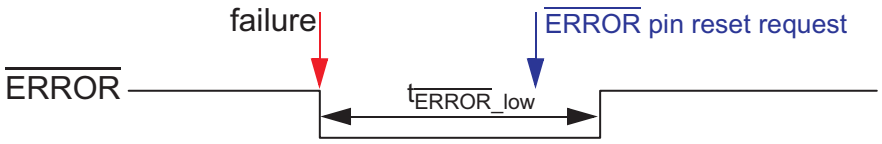
16.2.2 $\overline{\text{ERROR}}$ Pin Timing



The $\overline{\text{ERROR}}$ pin is an active low function. The state of the pin is also readable from $\overline{\text{ERROR}}$ Pin Status Register (ESMEPSR). A warm reset ($\overline{\text{RST}}$) does not affect the state of the pin. The pin is in a high-impedance state during power-on reset. Once the ESM module drives the $\overline{\text{ERROR}}$ pin low, it remains in this state for the time specified by the Low-Time Counter Preload register (LTCPR). Based on the time period of the peripheral clock (VCLK), the total active time of the $\overline{\text{ERROR}}$ pin can be calculated as:

$$t_{\overline{ERROR}\_low} = t_{VCLK} \times (LTCP + 1) \quad (22)$$

Once this period expires, the $\overline{\text{ERROR}}$ pin is set to high in case the reset of the $\overline{\text{ERROR}}$ pin was requested. This request is done by writing an appropriate key (0x5) to the key register (ESMEKR) during the $\overline{\text{ERROR}}$ pin low time. Here are a few examples:



Example 1: ESM detects a failure and drives the $\overline{\text{ERROR}}$ pin low. No $\overline{\text{ERROR}}$ pin reset is requested. The $\overline{\text{ERROR}}$ pin continues outputting low until power on reset occurs.

Figure 16-4. $\overline{\text{ERROR}}$ Pin Timing - Example 1

Example 2: ESM detects a failure and drives the $\overline{\text{ERROR}}$ pin low. An $\overline{\text{ERROR}}$ pin reset request is received before $t_{\overline{ERROR}\_low}$ expires. In this case, the $\overline{\text{ERROR}}$ pin is set to high immediately after $t_{\overline{ERROR}\_low}$ expires.

Figure 16-5. $\overline{\text{ERROR}}$ Pin Timing - Example 2

Example 3: ESM detects a failure and drives the $\overline{\text{ERROR}}$ pin low. An $\overline{\text{ERROR}}$ pin reset request is received after $t_{\overline{ERROR}\_low}$ expires. In this case, the $\overline{\text{ERROR}}$ pin is set to high immediately after $\overline{\text{ERROR}}$ pin reset request is received.

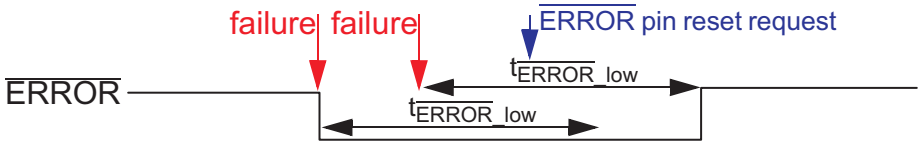


Figure 16-6. $\overline{\text{ERROR}}$ Pin Timing - Example 3

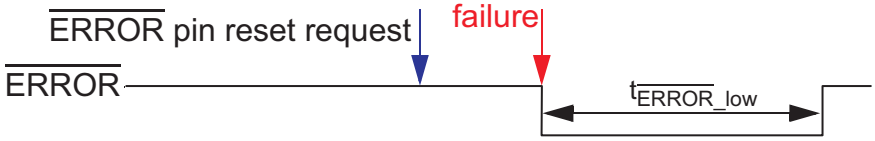
Copyright © 2018, Texas Instruments Incorporated



Example 4: ESM detects a failure and drives the $\overline{\text{ERROR}}$ pin low. Another failure occurs within the time the pin stays low. In this case, the low time counter will be reset when the other failure occurs. In other words, $t_{\overline{\text{ERROR}}\_low}$ should be counted from whenever the most recent failure occurs.

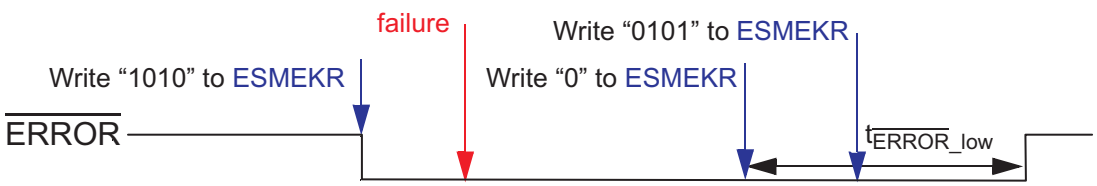
Figure 16-7. $\overline{\text{ERROR}}$ Pin Timing - Example 4

Example 5: The reset of the $\overline{\text{ERROR}}$ pin was requested by the software even before the failure occurs. In this case, the $\overline{\text{ERROR}}$ pin is set to high immediately after $t_{\overline{\text{ERROR}}\_low}$ expires. This case is not recommended and should be avoided by the application.

Figure 16-8. $\overline{\text{ERROR}}$ Pin Timing - Example 5

16.2.3 Forcing an Error Condition

The error response generation mechanism is testable by software by forcing an error condition. This allows testing the $\overline{\text{ERROR}}$ pin functionality. By writing a dedicated key to the error forcing key register (ESMEKR), the $\overline{\text{ERROR}}$ pin is set to low for the specified time. The following steps describe how to force an error condition:



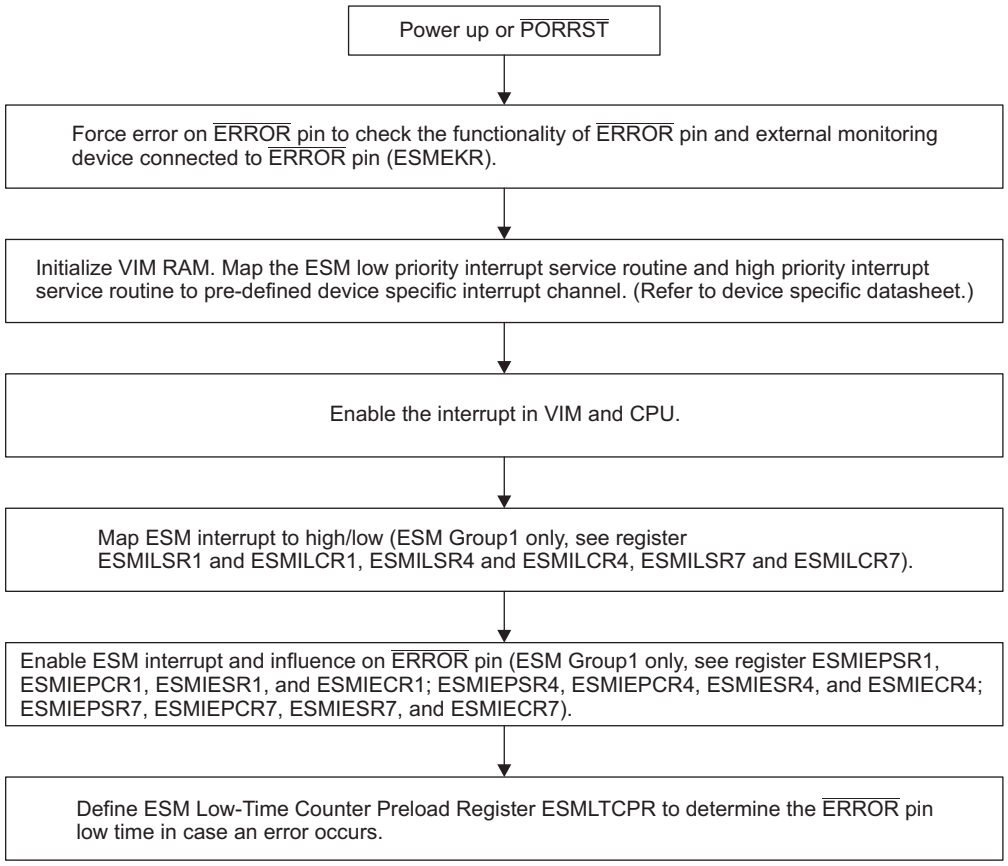
1. Check $\overline{\text{ERROR}}$ Pin Status Register (ESMEPSR). This register must be 1 to switch into the error forcing mode.

   The ESM module cannot be switched into the error forcing mode if a failure has already been detected in functional mode. The application command to switch to error forcing mode is ignored.
2. Write “1010b” to the error forcing key register (ESMEKR). After that, the $\overline{\text{ERROR}}$ pin should output low (error force mode).

   Once the application puts the ESM module in the error forcing mode, the $\overline{\text{ERROR}}$ pin cannot indicate the normal error functionality. If a failure occurs during this time, it gets still latched and the LTC is reset and stopped. The error output pin is already driven low on account of the error forcing mode. When the ESM is forced back to normal functional mode, the LTC becomes active and forces the $\overline{\text{ERROR}}$ pin low until the expiration of the LTC (see Figure 16-9).
3. Write “0000” to the error forcing key register (ESMEKR) back to the active normal mode.

   If there are no errors detected while the ESM module is in the error forcing mode, the $\overline{\text{ERROR}}$ pin goes high immediately after exiting the error forcing mode.

Figure 16-9. ERROR Pin Timing - Example 6



Copyright © 2018, Texas Instruments Incorporated

16.3 Recommended Programming Procedure

During the initialization stage, the application code should follow the recommendations in Figure 16-10 to initialize the ESM.

Once an error occurs, it can trigger an interrupt, $\overline{\text{ERROR}}$ pin outputs low depending on the ESM settings. Once the $\overline{\text{ERROR}}$ pin outputs low, a power on reset or a write of 0x5 to ESMEKR is required to release the ESM back to normal state. The application can read the error status registers (ESMSR1, ESMSR4, ESMSR7, ESMSR2, and ESMSR3) to debug the error. If an $\overline{\text{RST}}$ is triggered or the error interrupt has been served, the error flag of Group2 should be read from ESMSSR2 because the error flag in ESMSR2 will be cleared by $\overline{\text{RST}}$.

Real-Time Interrupt (RTI) Module

This chapter describes the functionality of the real-time interrupt (RTI) module. The RTI is designed as an operating system timer to support a real time operating system (RTOS).

NOTE: This chapter describes a superset implementation of the RTI module that includes features and functionality related to DMA, FlexRay, and Timbase control. These features are dependent on the device-specific feature content. Consult your device-specific datasheet to determine the applicability of these features to your device being used.

Topic **Page**

17.1 Overview **584**
17.2 Module Operation **585**
17.3 RTI Control Registers **595**

Copyright © 2018, Texas Instruments Incorporated

17.1 Overview

The real-time interrupt (RTI) module provides timer functionality for operating systems and for benchmarking code. The RTI module can incorporate several counters that define the timebases needed for scheduling in the operating system.

The timers also allow you to benchmark certain areas of code by reading the values of the counters at the beginning and the end of the desired code range and calculating the difference between the values.

In addition the RTI provides a mechanism to synchronize the operating system to the FlexRay communication cycle. Clock supervision allows for detection of issues on the FlexRay bus with an automatic switch to an internally generated timebase when a failure with the FlexRay timebase is detected.

17.1.1 Features

The RTI module has the following features:

- Two independent 64 bit counter blocks
- Four configurable compares for generating operating system ticks or DMA requests. Each event can be driven by either counter block 0 or counter block 1.
- One counter block usable for application synchronization to FlexRay network including clock supervision
- Fast enabling/disabling of events
- Two time stamp (capture) functions for system or peripheral interrupts, one for each counter block
- Digital windowed watchdog

17.1.2 Industry Standard Compliance Statement

This module is specifically designed to fulfill the requirements for OSEK (**O**ffene **S**ysteme und deren **S**chnittstellen für die **E**lektronik im **K**raftfahrzeug, or Open Systems and the Corresponding Interfaces for Automotive Electronics) as well as OSEK/time-compliant operating systems, but is not limited to it.

Copyright © 2018, Texas Instruments Incorporated

17.2 Module Operation

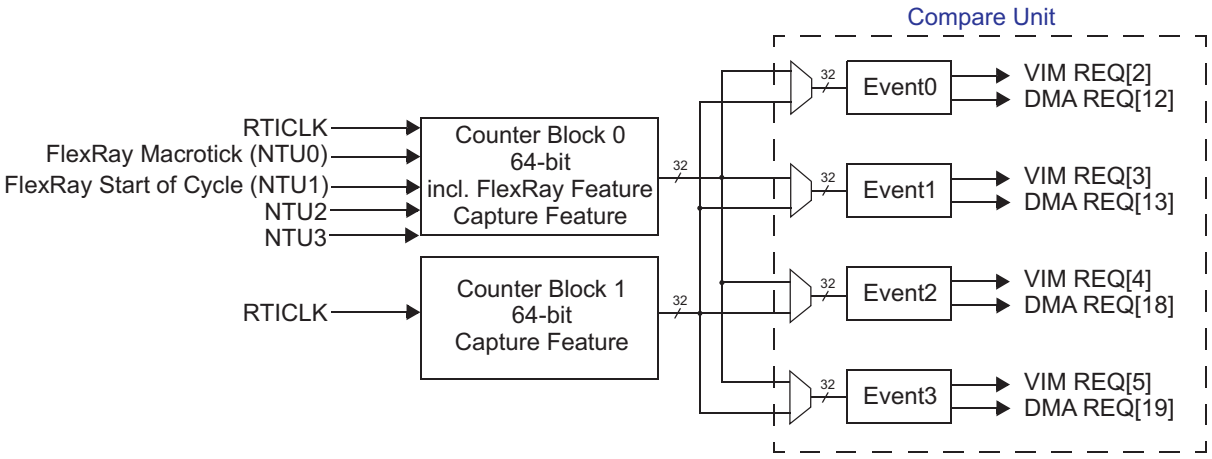

Figure 17-1 illustrates the high level block diagram of the RTI module.

The RTI module has two independent counter blocks for generating different timebases: counter block 0 and counter block 1. The two counter blocks provide the same basic functionality, but counter block 0 has the additional functionality of being able to work with the FlexRay Macrotick (NTU0) or Start of Cycle (NTU1) and perform clock supervision to detect a missing signal.

A compare unit compares the counters with programmable values and generates four independent interrupt or DMA requests on compare matches. Each of the compare registers can be programmed to be compared to either counter block 0 or counter block 1.

The following sections describe the individual functions in more detail.

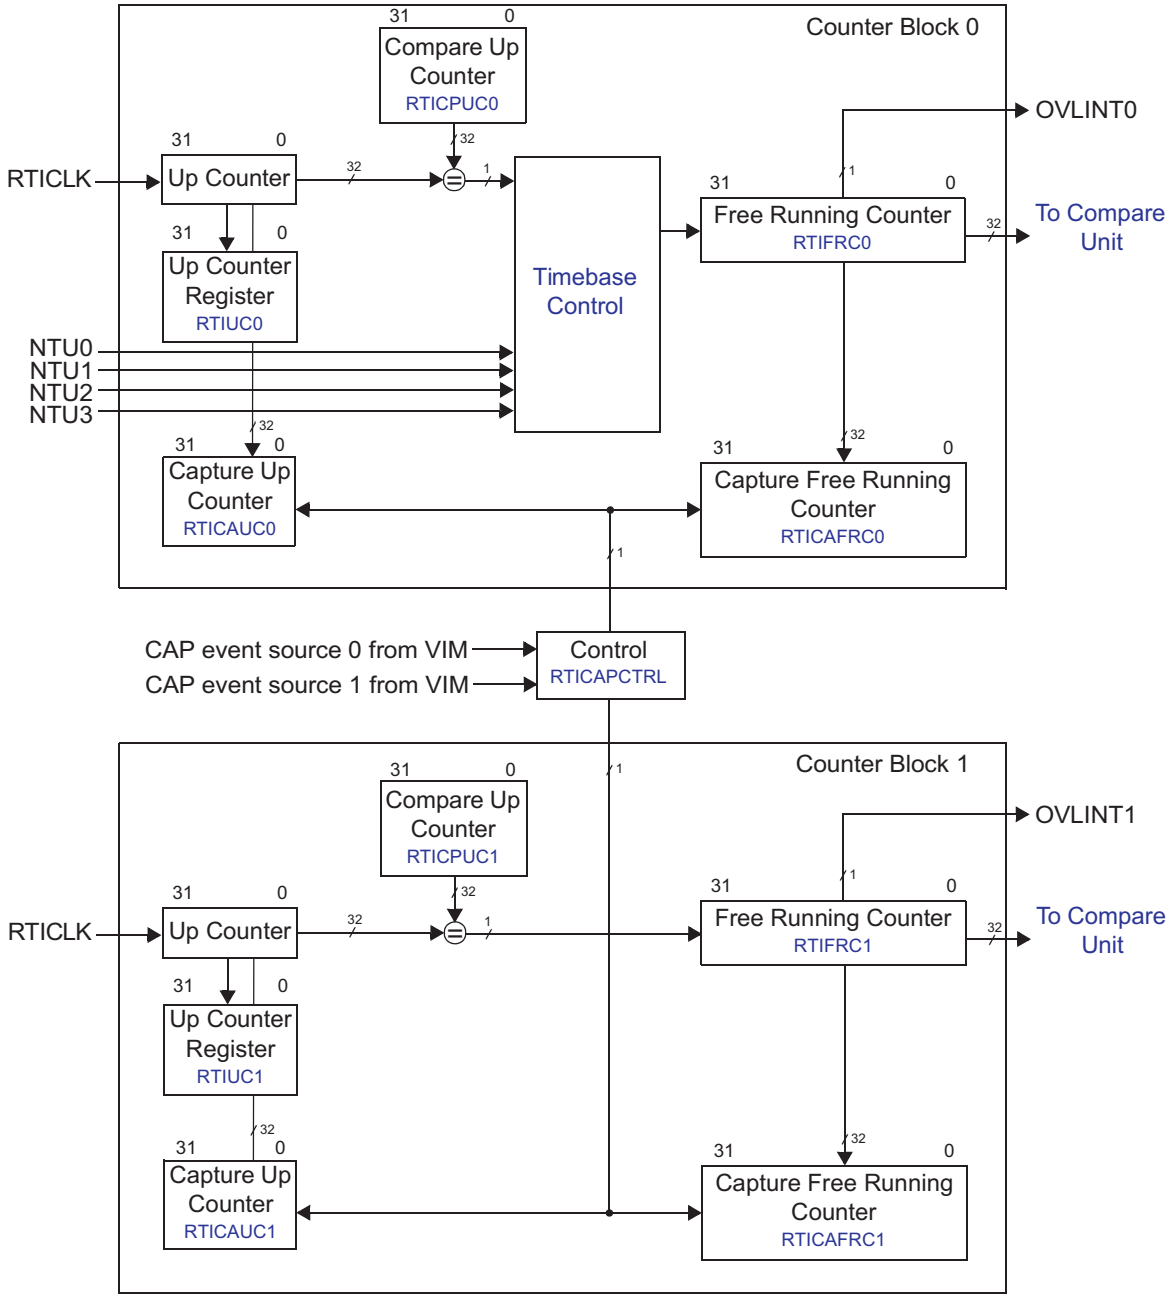
Figure 17-1. RTI Block Diagram

17.2.1 Counter Operation

Each counter block consists of the following (see Figure 17-2):

- One 32-bit prescale counter (RTIUC0 or RTIUC1)
- One 32-bit free running counter (RTIFRC0 or RTIFRC1)

The RTIUC0/1 is driven by the RTICLK and counts up until the compare value in the compare up counter register (RTICPUC0 or RTICPUC1) is reached. When the compare matches, RTIFRC0/1 is incremented and RTIUC0/1 is reset to 0. If RTIFRC0/1 overflows, an interrupt is generated to the vectored interrupt manager (VIM). The overflow interrupt is not intended to generate the timebase for the operating system. See Section 17.2.2 for the timebase generation. The up counter together with the compare up counter value prescale the RTI clock. The resulting formula for the frequency of the free running counter (RTIFRC0/1) is:



$$f_{RTIFRCx} = \begin{cases} \dfrac{f_{RTICLK}}{RTICPUCx + 1} & \text{when RTICPUCx} \neq 0 \\ \dfrac{f_{RTICLK}}{2^{32}+1} & \text{when RTICPUCx} = 0 \end{cases} \quad (23)$$

NOTE: Setting RTICPUCx equal to zero is not recommended. Doing so will hold the Up Counter at zero for two RTICLK cycles after it overflows from 0xFFFFFFFF to zero.

The counter values can be determined by reading the respective counter registers or by generating a hardware event which captures the counter value into the respective capture register. Both functions are described in the following sections.

Copyright © 2018, Texas Instruments Incorporated

Figure 17-2. Counter Block Diagram

17.2.1.1 Counter and Capture Read Consistency

Portions of the device internal databus are 32-bits wide. If the application wants to read the 64-bit counters or the 64-bit capture values, a certain order of 32-bit read operations needs to be followed. This is to prevent one counter incrementing in between the two separate read operations to both counters.

Reading the Counters

The free running counter (RTIFRCx) must be read first. This priority will ensure that in the cycle when the CPU reads RTIFRCx, the up counter value is stored in its counter register (RTIUCx). The second read has to access the up counter register (RTIUCx), which then holds the value which corresponds to the number of RTICLK cycles that have elapsed at the time reading the free running counter register (RTIFRCx).

NOTE: The up counters are implemented as shadow registers. Reading RTIUCx without having read RTIFRCx first will return always the same value. RTIUCx will only be updated when RTIFRCx is read.

Reading the Capture Values

The free running counter capture register (RTICAFRCx) must be read first. This priority will ensure that in the cycle when the CPU reads RTICAFRCx, the up counter value is stored in its counter register (RTICAUCx). The second read has to access the up counter register (RTICAUCx), which then holds the value captured at the time when reading the capture free running counter register (RTICAFRCx).

NOTE: The capture up counter registers are implemented as shadow registers. Reading RTICAUCx without having read RTICAFRCx first will return always the same value. RTICAUCx will only be updated when RTICAFRCx is read.

17.2.1.2 Capture Feature

Both counter blocks also provide a capture feature on external events. Two capture sources can trigger the capture event. The source triggering the block is configurable (RTICAPCTRL). The sources originate from the Vectored Interrupt Manager (VIM) and allow the generation of capture events when a peripheral modules has generated an interrupt. Any of the peripheral interrupts can be selected as the capture event in the VIM.

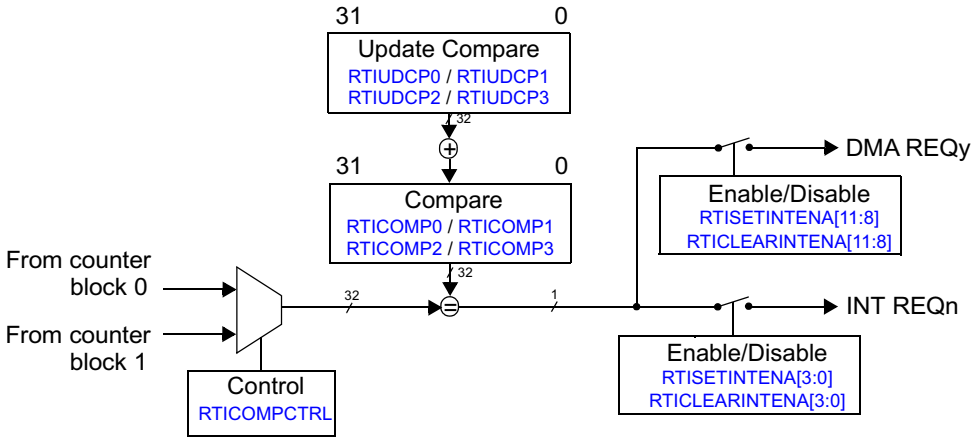
When an event is detected, RTIUCx and RTIFRCx are stored in the capture up counter (RTICAUCx) and capture free running counter (RTICAFRCx) registers. The read order of the captured values must be the same as the read order of the actual counters (see Section 17.2.1.1).

17.2.2 Interrupt/DMA Requests

There are four compare registers (RTICOMPy) to generate interrupt requests to the VIM or DMA requests to the DMA controller. The interrupts can be used to generate different timebases for the operating system. Each of the compare registers can be configured to be compared to either RTIFRC0 or RTIFRC1. When the counter value matches the compare value, an interrupt is generated. To allow periodic interrupts, a certain value can be added to the compare value in RTICOMPy automatically. This value is stored in the update compare register (RTIUDCPy) and will be added after a compare is matched. The period of the generated interrupt/DMA request can be calculated with:

$$t_{COMPx} = t_{RTICLK} \times (RTICPUCy + 1) \times RTIUDCPy$$

if RTICPUCy ≠ 0,



$$t_{COMPx} = t_{RTICLK} \times (2^{32}+1) \times RTIUDCPy$$

if RTIUDCPy = 0,

$$t_{COMPx} = t_{RTICLK} \times (RTICPUCy + 1) \times 2^{32} \quad (24)$$

Copyright © 2018, Texas Instruments Incorporated

Figure 17-3. Compare Unit Block Diagram (shows only 1 of 4 blocks for simplification)

Another interrupt that can be generated is the overflow interrupt (OVLINTx) in case the RTIFRCx counter overflows.

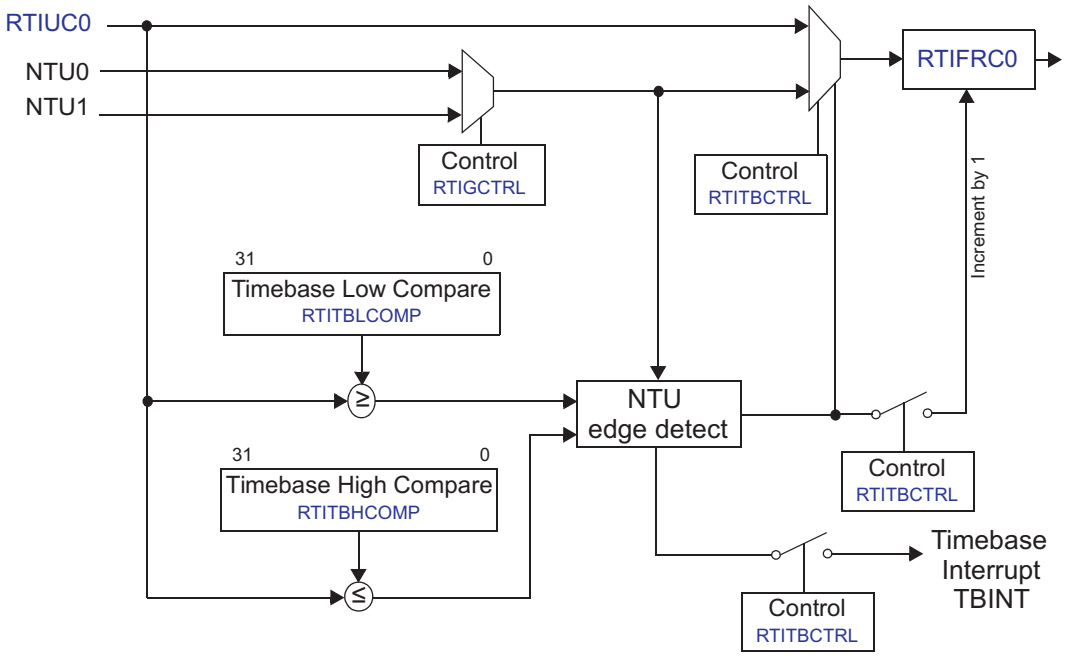
The interrupts/DMA requests can be enabled in the RTISETINTENA register and disabled in the RTICLEARINTENA register. The RTIINTFLAG register shows the pending interrupts.

17.2.3 RTI Clocking

The counter blocks are clocked with RTICLK (for definition see Section 2.4.2). Counter block 0 can be clocked in addition by either the FlexRay Macrotick (NTU0) or the FlexRay Start of Cycle (NTU1).

A clock supervision for the NTUx clocking scheme is implemented to avoid missing operating system ticks.

17.2.4 Synchronizing Timer Events to Network Time (NTU)



For applications which are participating on a time-triggered communication bus, it is often beneficial to synchronize the application or operating system to the network time. The RTI provides a feature to increment Free Running Counter 0 (RTIFRC0) by a periodic clock provided by the communication module. In this case two different clocks can be chosen. One is the FlexRay module Macrotick (NTU0) and the other is the Start of Cycle (NTU1) information of the same module.

The application has control over which clock (RTICLK, NTU0, NTU1) should be used for clocking RTIFRC0. If NTUx is used, a clock supervision circuit allows to monitor this clock and provides a fallback solution, should the clock be non-functional (missing). A too fast running NTUx cannot be detected.

RTIUC0 is utilized to monitor the NTUx signal. A detection window can be programmed in which a valid NTU clock pulse needs to occur. If no pulse is detected, the RTI automatically switches back to clock the Free Running Counter 0 with RTIUC0. In order to avoid a big jitter in the operating ticks, in case a switch back to RTIUC0 happens, RTICPUC0 should be set to a value so the clock frequency RTIUC0 outputs is approximately the same as the NTUx frequency.

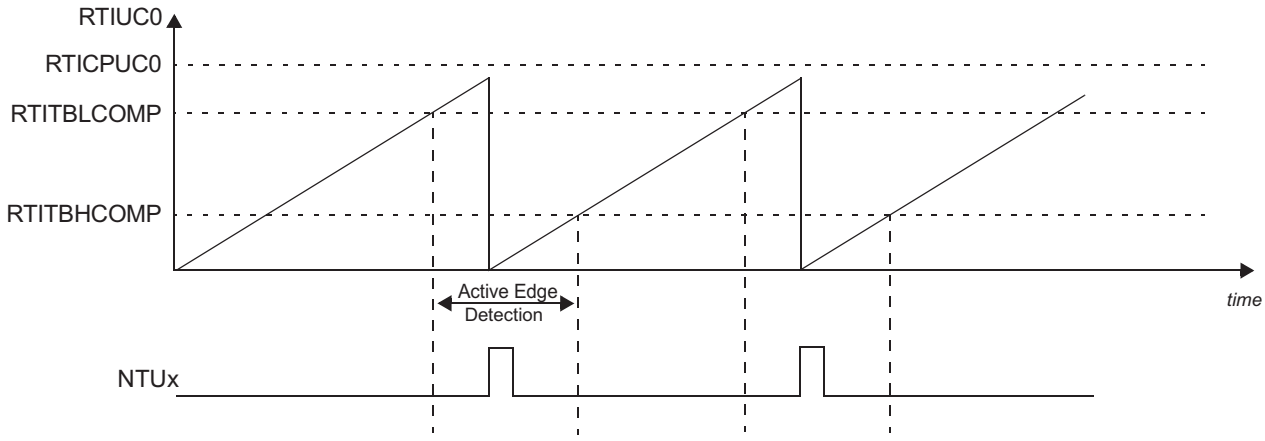
Figure 17-4. Timebase Control



17.2.4.1 Detecting Clock Edges

To detect clock edges on the NTUx signal, the timebase low compare has to be set lower or equal than the value stored in the RTICPUC0 register and the timebase high compare has to be set higher than 0 and lower than the timebase low compare value. This effectively opens a window in which an edge of the NTUx signal is expected (see Figure 17-5). Outside this window, no edges will be detected. If no edge will occur inside the detection window, the multiplexer is switched to internal timebase. The application can select to generate a timebase interrupt (TBINT) and if the INC bit is set, also will automatically increment RTIFRC0 by one to compensate for the missed clock cycle of NTUx. If an edge occurs inside the window, RTIUC0 will be reset to synchronize the two timebases.

In order to make the edge detection work properly, the value in RTICPUC0 needs to be adapted so that RTIUC0 has a similar period as NTUx.

NOTE: To ensure the NTUx signal is properly detected, the NTUx period must be at least twice as long as the RTICLK period.

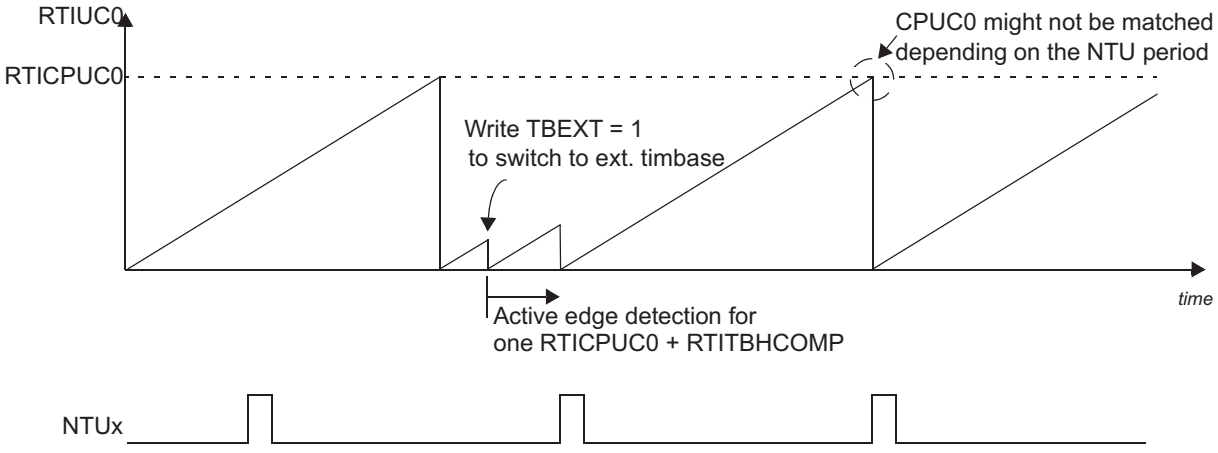
Figure 17-5. Clock Detection Scheme

Copyright © 2018, Texas Instruments Incorporated

17.2.4.2 Switching from Internal Source to External Source

If the application switches from an internal source to an external source, the two signals must be synchronized (see Figure 17-6). The synchronization will occur when the TBEXT bit is set. RTIUC0 will be reset and the edge detection circuit will be active for one (RTICPUC0 + RTITBHCOMP) period or until an edge is detected. If there is no pulse during this period, the source will be reset from an external clock source to an internal clock source. If an edge is detected, the windowed edge detection behavior will take place. Setting the TBEXT bit will not increment free running counter 0.

NOTE: If an external timebase is used, then the software must ensure that timebase low compare and timebase high compare are programmed to a valid state before switching TBEXT to an external source. This state is necessary to allow the timebase control circuit to operate correctly. The following condition must be met:



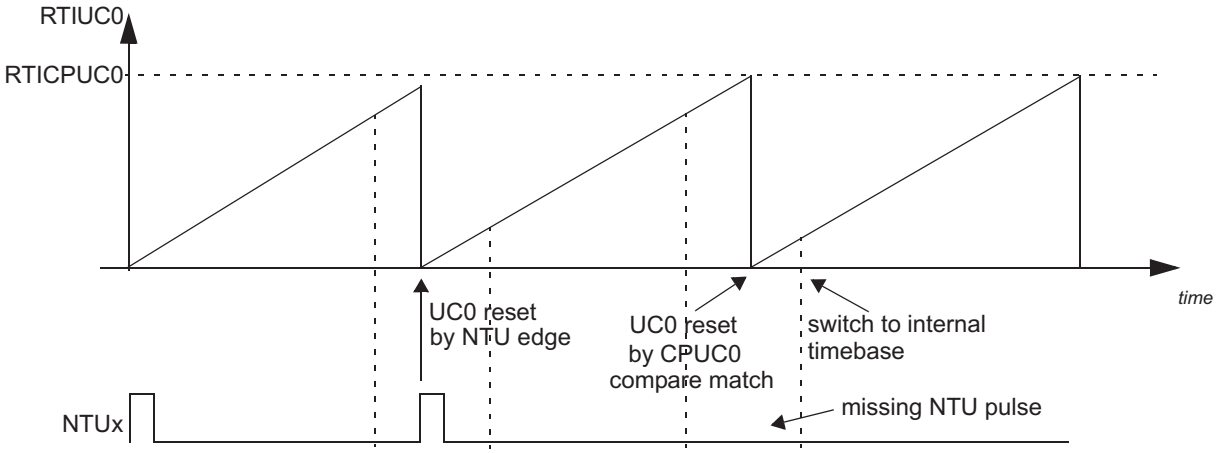
- RTITBHCOMP < RTITBLCOMP + RTICPUC0

RTITBHCOMP must be lower than RTICPUC0 because RTIUC0 will be reset if RTICPUC0 is reached. RTITBHCOMP will represent the number of RTICLK cycles from RTICPUC0 until the circuit switches to the internal timebase when no NTU edge is detected.

If an external timebase is used, RTIGCTRL[0] must be set to 1 (enable RTIUC0) to ensure that the timebase control circuit does not wait indefinitely for an incoming signal.

Figure 17-6 shows a timing example for the synchronization phase when the TBEXT bit is set.

Figure 17-6. Switch to NTUx



17.2.4.3 Switching from External Source to Internal Source

When the edge detection is active (TBEXT = 1) and no clock edge of NTUx is detected inside the programmed detection window, the RTI will automatically switch the timebase to RTIUC0. Figure 17-7 shows a timing example for a missing NTU signal. In the case where the INC bit is set, RTIFRC0 will automatically be incremented by one to compensate for the missed NTU pulse.

Setting TBEXT = 0 will also switch the clock source for RTIFRC0 to RTIUC0.

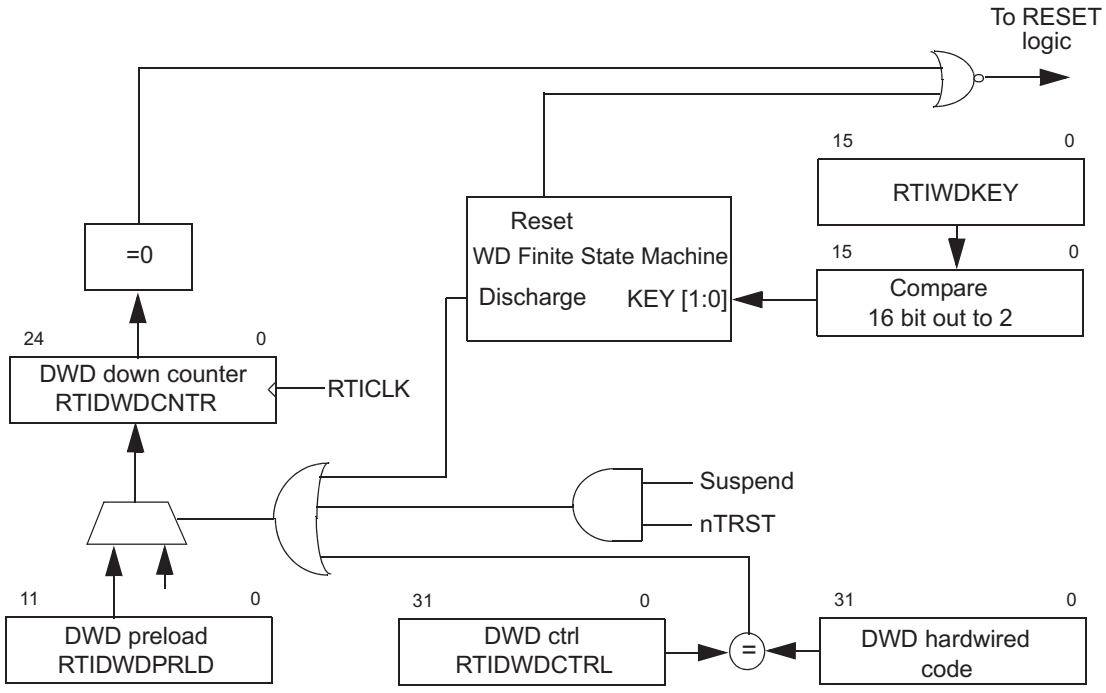

Figure 17-7. Missing NTUx Signal Example

17.2.5 Digital Watchdog (DWD)

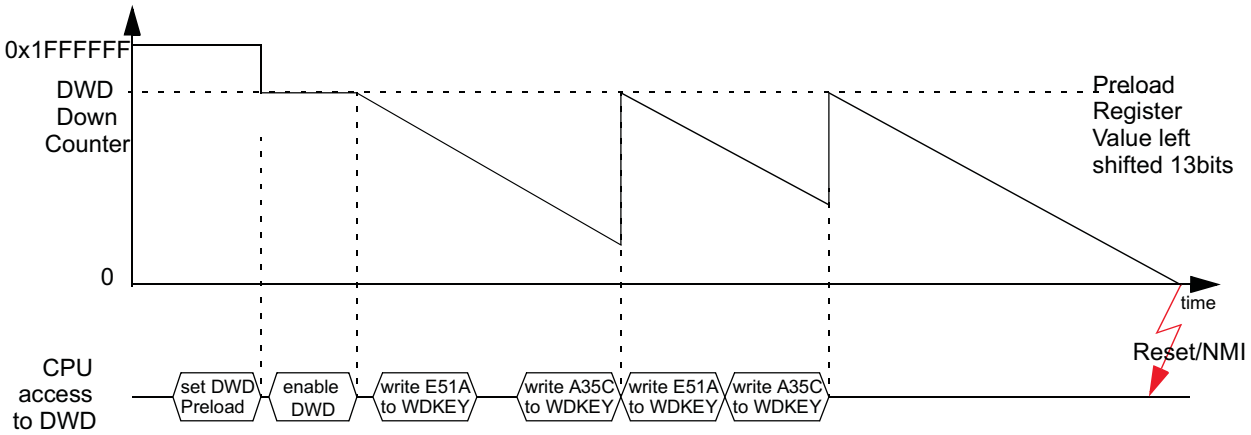
The digital watchdog (DWD) is an optional safety diagnostic which can detect a runaway CPU and generate either a reset or NMI (non-maskable interrupt) response. It generates resets or NMIs after a programmable period, or if no correct key sequence was written to the RTIWDKEY register. Figure 17-8 illustrates the DWD.

Figure 17-8. Digital Watchdog

Copyright © 2018, Texas Instruments Incorporated

17.2.5.1 Digital Watchdog (DWD)

The DWD is disabled by default. If it should be used, it must be enabled by writing a 32-bit value to the RTIDWDCTRL register.



NOTE: Once the DWD is enabled, it cannot be disabled except by system reset or power on reset.

If the correct key sequence is written to the RTIWDKEY register (0xE51A followed by 0xA35C), the 25-bit DWD down counter is reloaded with the left justified 12-bit preload value stored in RTIDWDPRLD. If an incorrect value is written, a watchdog reset or NMI will occur immediately. A reset or NMI will also be generated when the DWD down counter is decremented to 0.

While the device is in suspend mode (halting debug mode), the DWD down counter keeps the value it had when entering suspend mode.

The DWD down counter will be decremented with the RTICLK frequency.

Figure 17-9. DWD Operation

The expiration time of the DWD down counter can be determined with the following equation:

$texp = (DWDPRLD + 1) \times 2^{13}/RTICLK$

where

DWDPRLD = 0...4095

NOTE: Care should be taken to ensure that the CPU write to the watchdog register is made allowing time for the write to propagate to the RTI.

17.2.5.2 Digital Windowed Watchdog (DWWD)

In addition to the time-out boundary configurable via the digital watchdog discussed in Section 17.2.5.1, for enhanced safety metrics it is desirable to check for a watchdog "pet" within a time window rather than using a single time threshold. This is enabled by the digital windowed watchdog (DWWD) feature.

- Functional Behavior

The DWWD opens a configurable time window in which the watchdog must be serviced. Any attempt to service the watchdog outside this time window, or a failure to service the watchdog in this time window, will cause the watchdog to generate either a reset or a NMI to the CPU. This is controlled by configuring the RTIWWDRXNCTRL register. As with the DWD, the DWWD is disabled after power on reset. When the DWWD is configured to generate a non-maskable interrupt on a window violation, the watchdog counter continues to count down. The NMI handler needs to clear the watchdog violation status flag(s) and then

Copyright © 2018, Texas Instruments Incorporated

service the watchdog by writing the correct sequence in the watchdog key register. This service will cause the watchdog counter to get reloaded from the preload value and start counting down. If the NMI handler does not service the watchdog in time, it could count down all the way to zero and wrap around. If the NMI Handler does not service the watchdog in time, the NMI gets generated continuously, each time the counter counts to '0'.

The DWWD uses the Digital Watchdog (DWD) preload register (RTIDWDPRLD) setting to define the end-time of the window. The start-time of the window is defined by a window size configuration register(RTIWWDSIZECTRL).

The default window size is set to 100%, which corresponds to the DWD functionality of a time-out-only watchdog. The window size can be selected (through register RTIWWDSIZECTRL) from among 100%, 50%, 25%, 12.5%, 6.25% and 3.125% as shown in Figure 17-10. The window with the respective size will be opened before the end of the DWD expiration. The user has to serve the watchdog in the window. Otherwise, a reset or NMI will generate. Figure 17-11 shows an DWWD operation example (25% window).

- Configuration of DWWD

The DWWD preload value (same as DWD preload) can only be configured when the DWWD counter is disabled. The window size and watchdog reaction to a violation can be configured even after the watchdog has been enabled. Any changes to the window size and watchdog reaction configurations will only take effect after the next servicing of the DWWD. This feature can be utilized to dynamically set windows of different sizes based on task execution time, adding a program sequence element to the diagnostic which can improve fault coverage.

17.2.6 Low Power Modes

Low power modes allow the trade off of the current used during low power versus functionality and fast wakeup response. All low power modes have the following characteristics:

- CPU and system clocks are disabled.
- Flash banks and pump are in sleep mode.
- All peripheral modules are in low power modes and the clocks are disabled (exceptions to this may occur and would be documented in the specific device data sheet).

Flexibility in enabling and disabling clocks allows for many different low-power modes (see Section 2.4.3).

The operation of the RTI Module is guaranteed in Run, Doze and Snooze modes. In Sleep mode, all clocks will be switched off and the RTI will not work.

In Doze and Snooze modes, the RTI is active and is able to wake up the device with compare, timebase and overflow interrupts. The compare interrupts can be used to periodically wake up the device. The overflow interrupt can be used to notify the operating system that a counter overflow has occurred. Capturing events generated by the Vectored Interrupt Module (VIM) is also possible since, in both of these low power modes, the peripheral modules are able to generate interrupts that can trigger capture events. Capturing events while in Sleep mode is not supported as the clock to the RTI is not active.

When the device is put into low power mode, the peripheral which is generating the external clock NTU is no longer active, and the timebase control circuitry has to switch to an internal clocking scheme when it detects a missing clock on NTU. The timebase interrupt will wake up the device and the application software has to adapt the periodic interrupt generation to the internal clock source.

DMA transfers will be disabled, and DMA requests will not be generated after device wakeup since the DMA controller will be powered down.

NOTE: RTICLK in Doze Mode

In the special case of Doze Mode with PLL off, RTICLK might have a different period than with PLL enabled since RTICLK will be derived from the oscillator output. It has to be ensured that the VCLK to RTICLK ratio is at least 3:1.

17.2.7 Halting Debug Mode Behaviour

Once the system enters halting debug mode, the behavior of the RTI depends on the COS (continue on suspend) bit. If the bit is cleared and halting debug mode is active, all counters will stop operation. If the bit is set to one, all counters will be clocked normally and the RTI will work like in normal mode. However, if the external timebase (NTU) is used and the system is in halting debug mode, the timebase control circuit will switch to internal timebase once it detects the missing NTU signal of the suspended communication controller. This will be signaled with an TBINT interrupt so that software can resynchronize after the device exits halting debug mode.

NOTE: Writes to Reserved registers may clear the pending RTI interrupt.

17.3.1 RTI Global Control Register (RTIGCTRL)

The global control register starts/stops the counters and selects the signal compared with the timebase control circuit. This register is shown in Figure 17-12 and described in Table 17-2.

Figure 17-12. RTI Global Control Register (RTIGCTRL) [offset = 00]

31	20	19	16
Reserved		NTUSEL	
R-0		R/WP-0	

15	14	2	1	0
COS	Reserved		CNT1EN	CNT0EN
R/WP-0	R-0		R/WP-0	R/WP-0

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 17-2. RTI Global Control Register (RTIGCTRL) Field Descriptions

Bit	Field	Value	Description
31-20	Reserved	0	Reads return 0. Writes have no effect.
19-16	NTUSEL		Select NTU signal. These bits determine which NTU input signal is used as external timebase
		0h	NTU0
		5h	NTU1
		Ah	NTU2
		Fh	NTU3
		All other values	Tied to 0
15	COS		Continue on suspend. This bit determines if both counters are stopped when the device goes into halting debug mode or if they continue counting.
		0	Counters are stopped while in halting debug mode.
		1	Counters are running while in halting debug mode.
14-2	Reserved	0	Reads return 0. Writes have no effect.
1	CNT1EN		Counter 1 enable. This bit starts and stops counter block 1 (RTIUC1 and RTIFRC1).
		0	Counter block 1 is stopped.
		1	Counter block 1 is running.
0	CNT0EN		Counter 0 enable. This bit starts and stops counter block 0 (RTIUC0 and RTIFRC0).
		0	Counter block 0 is stopped.
		1	Counter block 0 is running.

NOTE: If the application uses the timebase circuit for synchronization between the communications controller and the operating system and the device enters halting debug mode, the synchronization may be lost depending on the COS setting in the RTI module and the halting debug mode behavior of the communications controller.

17.3.2 RTI Timebase Control Register (RTITBCTRL)

The timebase control register selects if the free running counter 0 is incremented by RTICLK or NTU. This register is shown in Figure 17-13 and described in Table 17-3.

Figure 17-13. RTI Timebase Control Register (RTITBCTRL) [offset = 04h]

Table 17-3. RTI Timebase Control Register (RTITBCTRL) Field Descriptions

Bit	Field	Value	Description
31-2	Reserved	0	Reads return 0. Writes have no effect.
1	INC		Increment free running counter 0. This bit determines whether the free running counter 0 (RTIFRC0) is automatically incremented if a failing clock on the NTU signal is detected.
		0	RTIFRC0 will not be incremented on a failing external clock.
		1	RTIFRC0 will be incremented on a failing external clock.
0	TBEXT		Timebase external. This bit selects whether the free running counter 0 (RTIFRC0) is clocked by the internal up counter 0 (RTIUC0) or from the external signal NTU. Setting the TBEXT bit from 0 to 1 will not increment RTIFRC0, since RTIUC0 is reset.
			When the timebase supervisor circuit detects a missing clock edge, then the TBEXT bit is reset.
			Only the software can select whether the external signal should be used.
		0	RTIUC0 clocks RTIFRC0.
		1	NTU clocks RTIFRC0.

Copyright © 2018, Texas Instruments Incorporated

17.3.3 RTI Capture Control Register (RTICAPCTRL)

The capture control register controls the capture source for the counters. This register is shown in Figure 17-14 and described in Table 17-4.

Figure 17-14. RTI Capture Control Register (RTICAPCTRL) [offset = 08h]

R/WP-0	

15	0
FRC0	
R/WP-0	

LEGEND: R/W = Read/Write; WP = Write in privileged mode only; -*n* = value after reset

Table 17-6. RTI Free Running Counter 0 Register (RTIFRC0) Field Descriptions

Bit	Field	Value	Description
31-0	FRC0	0-FFFF FFFFh	Free running counter 0. This registers holds the current value of the free running counter 0. A read of this counter returns the current value of the counter. The counter can be preset by writing (in privileged mode only) to this register. The counter increments then from this written value upwards. **Note: If counters must be preset, they must be disabled in the RTIGCTRL register to ensure consistency between RTIUC0 and RTIFRC0.**

17.3.6 RTI Up Counter 0 Register (RTIUC0)

The up counter 0 register holds the current value of prescale counter. This register is shown in Figure 17-17 and described in Table 17-7.

Figure 17-17. RTI Up Counter 0 Register (RTIUC0) [offset = 14h]

31	16

LLEGEND: R/W = Read/Write; WP = Write in privileged mode only; -*n* = value after reset

Table 17-7. RTI Up Counter 0 Register (RTIUC0) Field Descriptions

Bit	Field	Value	Description
31-0	UC0	0-FFFF FFFFh	Up counter 0. This register holds the current value of the up counter 0 and prescales the RTI clock. It will be only updated by a previous read of free running counter 0 (RTIFRC0). This method of updating effectively gives a 64-bit read of both counters, without having the problem of a counter being updated between two consecutive reads on up counter 0 (RTIUC0) and free running counter 0 (RTIFRC0). A read of this counter returns the value of the counter at the time RTIFRC0 was read. A write to this counter presets it with a value. The counter then increments from this written value upwards. Note: If counters must be preset, they must be disabled in the RTIGCTRL register to ensure consistency between RTIUC0 and RTIFRC0. **Note: If the preset value is bigger than the compare value stored in register RTICPUC0, then it can take a long time until a compare matches, since RTIUC0 has to count up until it overflows.**

Copyright © 2018, Texas Instruments Incorporated

17.3.7 RTI Compare Up Counter 0 Register (RTICPUC0)

The compare up counter 0 register holds the value to be compared with prescale counter 0 (RTIUC0). This register is shown in Figure 17-18 and described in Table 17-8.

Figure 17-18. RTI Compare Up Counter 0 Register (RTICPUC0) [offset = 18h]

31	16
CPUC0	
R/WP-0	

15	0
CPUC0	
R/WP-0	

LEGEND: R/W = Read/Write; WP = Write in privileged mode only; -*n* = value after reset

Table 17-8. RTI Compare Up Counter 0 Register (RTICPUC0) Field Descriptions

Bit	Field	Value	Description
31-0	CPUC0	0-FFFF FFFFh	Compare up counter 0. This register holds the value that is compared with the up counter 0. When the compare shows a match, the free running counter 0 (RTIFRC0) is incremented. RTIUC0 is set to 0 when the counter value matches the RTICPUC0 value. The value set in this register prescales the RTI clock. If CPUC0 = 0, then f_{FRC0} = RTICLK/(2^{32}+1) (Setting CPUC0 equal to 0 is not recommended. Doing so will hold the Up Counter at 0 for 2 RTICLK cycles after it overflows from FFFF FFFFh to 0.) If CPUC0 ≠ 0, then f_{FRC0} = RTICLK/(RTICPUC0+1) A read of this register returns the current compare value. A write to this register: • If TBEXT = 0, the compare value is updated. • If TBEXT = 1, the compare value is unchanged.

17.3.8 RTI Capture Free Running Counter 0 Register (RTICAFRC0)

The capture free running counter 0 register holds the free running counter 0 on external events. This register is shown in Figure 17-19 and described in Table 17-9.

Figure 17-19. RTI Capture Free Running Counter 0 Register (RTICAFRC0) [offset = 20h]

Table 17-9. RTI Capture Free Running Counter 0 Register (RTICAFRC0) Field Descriptions

Bit	Field	Value	Description
31-0	CAFRC0	0-FFFF FFFFh	Capture free running counter 0. This register captures the current value of the free running counter 0 (RTIFRC0) when an event occurs, controlled by the external capture control block. A read of this register returns the value of RTIFRC0 on a capture event.

Copyright © 2018, Texas Instruments Incorporated

17.3.9 RTI Capture Up Counter 0 Register (RTICAUC0)

The capture up counter 0 register holds the current value of prescale counter 0 on external events. This register is shown in Figure 17-20 and described in Table 17-10.

Figure 17-20. RTI Capture Up Counter 0 Register (RTICAUC0) [offset = 24h]

LEGEND: R = Read only; -*n* = value after reset

Table 17-10. RTI Capture Up Counter 0 Register (RTICAUC0) Field Descriptions

Bit	Field	Value	Description
31-0	CAUC0	0-FFFF FFFFh	Capture up counter 0. This register captures the current value of the up counter 0 (RTIUC0) when an event occurs, controlled by the external capture control block. **Note: The read sequence must be the same as with RTIUC0 and RTIFRC0. Therefore, the RTICAFRC0 register must be read before the RTICAUC0 register is read. This sequence ensures that the value of the RTICAUC0 register is the corresponding value to the RTICAFRC0 register, even if another capture event happens in between the two reads.** A read of this register returns the value of RTIUC0 on a capture event.

17.3.10 RTI Free Running Counter 1 Register (RTIFRC1)

The free running counter 1 register holds the current value of the free running counter 1. This register is shown in Figure 17-21 and described in Table 17-11.

Figure 17-21. RTI Free Running Counter 1 Register (RTIFRC1) [offset = 30h]

Table 17-11. RTI Free Running Counter 1 Register (RTIFRC1) Field Descriptions

Bit	Field	Value	Description
31-0	FRC1	0-FFFF FFFFh	Free running counter 1. This register holds the current value of the free running counter 1 and will be updated continuously. A read of this register returns the current value of the counter. A write to this register presets the counter. The counter increments then from this written value upwards. **Note: If counters must be preset, they must be disabled in the RTIGCTRL register to ensure consistency between RTIUC1 and RTIFRC1.**

Copyright © 2018, Texas Instruments Incorporated

17.3.11 RTI Up Counter 1 Register (RTIUC1)

The up counter 1 register holds the current value of the prescale counter 1. This register is shown in Figure 17-22 and described in Table 17-12.

Figure 17-22. RTI Up Counter 1 Register (RTIUC1) [offset = 34h]

31	16
UC1

LEGEND: R/W = Read/Write; WP = Write in privileged mode only; -*n* = value after reset

Table 17-12. RTI Up Counter 1 Register (RTIUC1) Field Descriptions

Bit	Field	Value	Description
31-0	UC1	0-FFFF FFFFh	Up counter 1. This register holds the current value of the up counter 1 and prescales the RTI clock. It will be only updated by a previous read of free running counter 1 (RTIFRC1). This method of updating effectively gives a 64-bit read of both counters, without having the problem of a counter being updated between two consecutive reads on RTIUC1 and RTIFRC1. A read of this register will return the value of the counter when the RTIFRC1 was read. A write to this register presets the counter. The counter then increments from this written value upwards. **Note: If counters must be preset, they must be disabled in the RTIGCTRL register to ensure consistency between RTIUC1 and RTIFRC1.** **Note: If the preset value is bigger than the compare value stored in register RTICPUC1, then it can take a long time until a compare matches, since RTIUC1 has to count up until it overflows.**

Copyright © 2018, Texas Instruments Incorporated

17.3.12 RTI Compare Up Counter 1 Register (RTICPUC1)

The compare up counter 1 register holds the value compared with prescale counter 1. This register is shown in Figure 17-23 and described in Table 17-13.

Figure 17-23. RTI Compare Up Counter 1 Register (RTICPUC1) [offset = 38h]

LEGEND: R/W = Read/Write; WP = Write in privileged mode only; -*n* = value after reset

Table 17-13. RTI Compare Up Counter 1 Register (RTICPUC1) Field Descriptions

Bit	Field	Value	Description
31-0	CPUC1	0-FFFF FFFFh	Compare up counter 1. This register holds the compare value, which is compared with the up counter 1. When the compare matches, the free running counter 1 (RTIFRC1) is incremented. The up counter is cleared to 0 when the counter value matches the CPUC1 value. The value set in this prescales the RTI clock according to the following formula: If CPUC1 = 0, then f_{FRC1} = RTICLK/(2^{32}+1) (Setting CPUC1 equal to 0 is not recommended. Doing so will hold the Up Counter at 0 for 2 RTICLK cycles after it overflows from FFFF FFFFh to 0.) If CPUC1 ≠ 0, then f_{FRC1} = RTICLK/(RTICPUC1+1) A read of this register returns the current compare value. A write to this register updates the compare value.

17.3.13 RTI Capture Free Running Counter 1 Register (RTICAFRC1)

The capture free running counter 1 register holds the current value of free running counter 1 on external events. This register is shown in Figure 17-24 and described in Table 17-14.

Figure 17-24. RTI Capture Free Running Counter 1 Register (RTICAFRC1) [offset = 40h]

31-0	COMP0	0-FFFF FFFFh	Compare 0. This registers holds a value that is compared with the counter selected in the compare control logic. If RTIFRC0 or RTIFRC1, depending on the counter selected, matches the compare value, an interrupt is flagged. With this register it is also possible to initiate a DMA request. A read of this register will return the current compare value. A write to this register (in privileged mode only) will update the compare register with a new compare value.

17.3.16 RTI Update Compare 0 Register (RTIUDCP0)

The update compare 0 register holds the value to be added to the compare register 0 value on a compare match. This register is shown in Figure 17-27 and described in Table 17-17.

17.3.23 RTI Timebase Low Compare Register (RTITBLCOMP)

The timebase low compare register holds the value to activate the edge detection circuit. This register is shown in Figure 17-34 and described in Table 17-24.

Figure 17-34. RTI Timebase Low Compare Register (RTITBLCOMP) [offset = 70h]

31	16
TBLCOMP	
R/WP-0	

15	0
TBLCOMP	
R/WP-0	

LEGEND: R/W = Read/Write; WP = Write in privileged mode only; -*n* = value after reset

Table 17-24. RTI Timebase Low Compare Register (RTITBLCOMP) Field Descriptions

Bit	Field	Value	Description
31-0	TBLCOMP	0-FFFF FFFFh	Timebase low compare value. This value determines when the edge detection circuit starts monitoring the NTU signal. It will be compared with RTIUC0. A read of this register will return the current compare value. A write to this register has the following effects: If TBEXT = 0: The compare value is updated. If TBEXT = 1: The compare value is not changed.

17.3.24 RTI Timebase High Compare Register (RTITBHCOMP)

The timebase high compare register holds the value to deactivate the edge detection circuit. This register is shown in Figure 17-35 and described in Table 17-25.

Table 17-25. RTI Timebase High Compare Register (RTITBHCOMP) Field Descriptions

Bit	Field	Value	Description
31-0	TBHCOMP	0-FFFF FFFFh	Timebase high compare value. This value determines when the edge detection circuit will stop monitoring the NTU signal. It will be compared with RTIUC0. RTITBHCOMP must be less than RTICPUC0 because RTIUC0 will be reset when RTICPUC0 is reached. Example: The NTU edge detection circuit should be active ± 10 RTICLK cycles around RTICPUC0. • RTICPUC0 = 0050h • RTITBLCOMP = 0046h • RTITBHCOMP = 0009h A read of this register will return the current compare value. A write to this register has the following effects: If TBEXT = 0: The compare value is updated. If TBEXT = 1: The compare value is not changed.

17.3.27 RTI Interrupt Flag Register (RTIINTFLAG)

The corresponding flags are set at every compare match of the RTIFRCx and RTICOMPx values, whether the interrupt is enabled or not. This register is shown in Figure 17-38 and described in Table 17-28.

Figure 17-38. RTI Interrupt Flag Register (RTIINTFLAG) [offset = 88h]

31	19	18	17	16
Reserved		OVL1INT	OVL0INT	TBINT
R-0		R/W1CP-0	R/W1CP-0	R/W1CP-0

15	4	3	2	1	0
Reserved		INT3	INT2	INT1	INT0
R-0		R/W1CP-0	R/W1CP-0	R/W1CP-0	R/W1CP-0

LEGEND: R/W = Read/Write; R = Read only; W1CP = Write 1 to clear in privilege mode only; -*n* = value after reset

Table 17-28. RTI Interrupt Flag Register (RTIINTFLAG) Field Descriptions

Bit	Field	Value	Description
31-19	Reserved	0	Reads return 0. Writes have no effect.
18	OVL1INT		Free running counter 1 overflow interrupt flag. This bit determines if an interrupt is pending.
		0	*Read:* No interrupt is pending. *Write:* Bit is unchanged.
		1	*Read:* Interrupt is pending. *Write:* Bit is cleared to 0.
17	OVL0INT		Free running counter 0 overflow interrupt flag. This bit determines if an interrupt is pending.
		0	*Read:* No interrupt is pending. *Write:* Bit is unchanged.
		1	*Read:* Interrupt is pending. *Write:* Bit is cleared to 0.
16	TBINT		Timebase interrupt flag. This flag is set when the TBEXT bit is cleared by detection of a missing external clock edge. It will not be set by clearing TBEXT by software. It determines if an interrupt is pending.
		0	*Read:* No interrupt is pending. *Write:* Bit is unchanged.
		1	*Read:* Interrupt is pending. *Write:* Bit is cleared to 0.
15-4	Reserved	0	Reads return 0. Writes have no effect.
3	INT3		Interrupt flag 3. These bits determine if an interrupt due to a Compare 3 match is pending.
		0	*Read:* No interrupt is pending. *Write:* Bit is unchanged.
		1	*Read:* Interrupt is pending. *Write:* Bit is cleared to 0.
2	INT2		Interrupt flag 2. These bits determine if an interrupt due to a Compare 2 match is pending.
		0	*Read:* No interrupt is pending. *Write:* Bit is unchanged.
		1	*Read:* Interrupt is pending. *Write:* Bit is cleared to 0.
1	INT1		Interrupt flag 1. These bits determine if an interrupt due to a Compare 1 match is pending.
		0	*Read:* No interrupt is pending. *Write:* Bit is unchanged.
		1	*Read:* Interrupt is pending. *Write:* Bit is cleared to 0.

Table 17-28. RTI Interrupt Flag Register (RTIINTFLAG) Field Descriptions (continued)

Bit	Field	Value	Description
0	INT0	0	Interrupt flag 0. These bits determine if an interrupt due to a Compare 0 match is pending. *Read:* No interrupt is pending. *Write:* Bit is unchanged.
		1	*Read:* Interrupt is pending. *Write:* Bit is cleared to 0.

17.3.28 Digital Watchdog Control Register (RTIDWDCTRL)

The software has to write to the DWDCTRL field in order to enable the DWD, as described below. Once enabled, the watchdog can only be disabled by a system reset. The application cannot disable the watchdog. However should the RTICLK source be changed to a source that is unimplemented it will have the same effect as disabling the watchdog. This register is shown in Figure 17-38 and described in Table 17-28.

Figure 17-39. Digital Watchdog Control Register (RTIDWDCTRL) [offset = 90h]

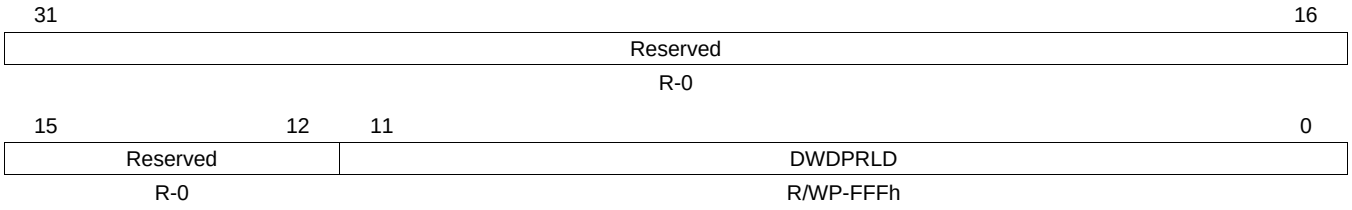
R/WP-ACEDh	

LEGEND: R/W = Read/Write; WP = Write in privileged mode only; *-n* = value after reset

Table 17-29. Digital Watchdog Control Register (RTIDWDCTRL) Field Descriptions



Bit	Field	Value	Description
31-0	DWDCTRL	5312 ACEDh	Digital Watchdog Control. *Read:* DWD counter is disabled. *Write:* State of DWD counter is unchanged (stays enabled or disabled).
		A985 59DAh	*Read:* DWD counter is enabled. *Write:* DWD counter is enabled.
		All other values	*Read:* DWD counter state is unchanged (enabled or disabled). *Write:* State of DWD counter is unchanged (stays enabled or disabled). **Note:** Once the enable value is written, all other future writes are blocked. In other words, once DWD is enabled, it can only be disabled by system reset or power on reset. However should the RTICLK source be changed to a source that is unimplemented it will have the same effect as disabling the watchdog.

17.3.29 Digital Watchdog Preload Register (RTIDWDPRLD)

This register sets the expiration time of the DWD. This register is shown in Figure 17-38 and described in Table 17-28.

Figure 17-40. Digital Watchdog Preload Register (RTIDWDPRLD) [offset = 94h]

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 17-30. Digital Watchdog Preload Register (RTIDWDPRLD) Field Descriptions

Bit	Field	Value	Description
31-12	Reserved	0	Reads return 0 and writes have no effect.
11-0	DWDPRLD	0-FFFh	Digital Watchdog Preload Value. *Read:* The current preload value *Write:* Set the preload value. The DWD preload register can be configured only when the DWD is disabled. Therefore, the application can only configure the DWD preload register before it enables the DWD down counter. The expiration time of the DWD Down Counter can be determined with following equation: texp = (DWDPRLD+1) x 2^{13} / RTICLK1 where: DWDPRLD = 0...4095

17.3.30 Watchdog Status Register (RTIWDSTATUS)

This register records the status of the DWD. The values of the following status bits will not be affected by a soft reset. These bits are cleared by a power-on reset, or by a write of 1. These bits can be used for debug purposes. This register is shown in Figure 17-38 and described in Table 17-28.

Figure 17-41. Watchdog Status Register (RTIWDSTATUS) [offset = 98h]

31							8
Reserved							
R-0							
7	6	5	4	3	2	1	0
Reserved		DWWD ST	END TIME VIOL	START TIME VIOL	KEY ST	DWD ST	Reserved
R-0		R/W1CP-x	R/W1CP-x	R/W1CP-x	R/W1CP-x	R/W1CP-x	R-0

LEGEND: R/W = Read/Write; R = Read only; W1CP = Write 1 to clear in privilege mode only; -*n* = value after reset

Table 17-31. Watchdog Status Register (RTIWDSTATUS) Field Descriptions

Bit	Field	Value	Description
31-6	Reserved	0	Reads return 0. Writes have no effect.
5	DWWD ST		Windowed Watchdog Status
		0	*Read:* No time-window violation has occurred. *Write:* Leaves the current value unchanged.
		1	*Read:* Time-window violation has occurred. The watchdog has generated either a system reset or a non-maskable interrupt to the CPU in this case. *Write:* Bit is cleared to 0. This will also clear all other status flags in the RTIWDSTATUS register. Clearing of the status flags will deassert the non-maskable interrupt generated due to violation of the DWWD.
4	END TIME VIOL		Windowed Watchdog End Time Violation Status. This bit indicates whether the Watchdog counter expired.
		0	*Read:* No end-time window violation has occurred. *Write:* Leaves the current value unchanged.
		1	*Read*: End-time defined by the windowed watchdog configuration has been violated. *Write:* Bit is cleared to 0.
3	START TIME VIOL		Windowed Watchdog Start Time Violation Status. This bit indicates whether the key is written before the watchdog window opened up.
		0	*Read:* No start-time window violation has occurred. *Write:* Leaves the current value unchanged.
		1	*Read:* Start-time defined by the windowed watchdog configuration has been violated. *Write:* Bit is cleared to 0.
2	KEY ST		Watchdog key status. This bit indicates a reset or NMI generated by a wrong key or key sequence written to the RTIWDKEY register.
		0	*Read:* No wrong key or key-sequence written. *Write:* Bit is unchanged.
		1	*Read:* Wrong key or key-sequence written to RTIWDKEY register. *Write:* Bit is cleared to 0.
1	DWD ST		DWD status. This bit is equivalent to bit END TIME VIOL.
		0	*Read:* No reset or NMI was generated. *Write:* Bit is unchanged.
		1	*Read:* Reset or NMI was generated. *Write:* Bit is cleared to 0.
0	Reserved	0	Reads return 0. Writes have no effect.

17.3.31 RTI Watchdog Key Register (RTIWDKEY)

This register must be written with the correct written key values to serve the watchdog. This register is shown in Figure 17-42 and described in Table 17-32.

NOTE: It has to be taken into account that the write to the RTIWDKEY register takes 3 VCLK cycles.

Figure 17-42. RTI Watchdog Key Register (RTIDWDKEY) [offset = 9Ch]

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privileged mode only; -*n* = value after reset

Table 17-32. RTI Watchdog Key Register (RTIDWDKEY) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0 and writes have no effect.
15-0	WDKEY	0-FFFFh	Watchdog key. These bits provide the key sequence location. Reads returns the current WDKEY value. A write of E51Ah followed by A35Ch in two separate write operations defines the key sequence and reloads the DWD. Writing any other value causes a reset or NMI, as shown in Table 17-33. Writing any other value will cause the WDKEY to reset to A35Ch.

Table 17-33. Example of a WDKEY Sequence

Step	Value Written to WDKEY	Result
1	A35Ch	No action
2	A35Ch	No action
3	E51Ah	WDKEY is enabled for reset or NMI by next A35Ch.
4	E51Ah	WDKEY is enabled for reset or NMI by next A35Ch.
5	E51Ah	WDKEY is enabled for reset or NMI by next A35Ch.
6	A35Ch	Watchdog is reset.
7	A35Ch	No action
8	E51Ah	WDKEY is enabled for reset or NMI by next A35Ch.
9	A35Ch	Watchdog is reset.
10	E51Ah	WDKEY is enabled for reset or NMI by next A35Ch.
11	2345h	System reset or NMI; incorrect value written to WDKEY.

Table 17-35. Digital Windowed Watchdog Reaction Control (RTIWWDRXNCTRL) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reads return 0 and writes have no effect.
3-0	WWDRXN		The DWWD reaction
		5h	The windowed watchdog will cause a reset if the watchdog is serviced outside the time window defined by the configuration, or if the watchdog is not serviced at all.
		Ah	The windowed watchdog will generate a non-maskable interrupt to the CPU if the watchdog is serviced outside the time window defined by the configuration, or if the watchdog is not serviced at all.
		All other values	The windowed watchdog will cause a reset if the watchdog is serviced outside the time window defined by the configuration, or if the watchdog is not serviced at all.
			Note: The DWWD reaction can be selected by the application even when the DWWD counter is already enabled. If a change to the WWDRXN is made before the watchdog service window is opened, then the change in the configuration takes effect immediately. If a change to the WWDRXN is made when the watchdog service window is already open, then the change in configuration takes effect only after the watchdog is serviced.

Table 17-36. Digital Windowed Watchdog Window Size Control (RTIWWDSIZECTRL) Field Descriptions

Bit	Field	Value	Description
31-0	WWDSIZE	0	The DWWD window size
		0000 0005h	100% (The functionality is the same as the standard time-out digital watchdog.)
		0000 0050h	50%
		0000 0500h	25%
		0000 5000h	12.5%
		0005 0000h	6.25%
		All other values	3.125%
			Note: The DWWD window size can be selected by the application even when the DWWD counter is already enabled. If a change to the WWDSIZE is made before the watchdog service window is opened, then the change in the configuration takes effect immediately. If a change to the WWDSIZE is made when the watchdog service window is already open, then the change in configuration takes effect only after the watchdog is serviced.

17.3.35 RTI Compare Interrupt Clear Enable Register (RTIINTCLRENABLE)

When the RTI compare event is configured to generate a DMA request or triggers (all triggered by RTI compare interrupt request flag) to other peripherals, it is often desirable to clear the RTI compare flag automatically so that the requests can be generated repeatedly without any CPU intervention. This register works with the RTI compare clear registers to enable an "auto-clear" of the compare interrupt enable bit after a compare equal event. This register is shown in Figure 17-46 and described in Table 17-37.

Figure 17-46. RTI Compare Interrupt Clear Enable Register (RTIINTCLRENABLE) [offset = ACh]

17.3.36 RTI Compare 0 Clear Register (RTICMP0CLR)

This registers holds an initial value which is larger than the value in the RTI Compare 0 register Section 17.3.4. The user needs to choose the value such that the compare clear 0 event occurs before next compare 0 event. If the Free Running Counter matches the compare value, the compare 0 interrupt request flag is cleared and the value in the RTIUDCP0 register Section 17.3.16 is added to this register. This register is shown in Figure 17-47 and described in Table 17-38.

Cyclic Redundancy Check (CRC) Controller Module

This chapter describes the cyclic redundancy check (CRC) controller module.

NOTE: This chapter describes a superset implementation of the CRC module that includes features and functionality that require DMA. Since not all devices have DMA capability, consult your device-specific datasheet to determine applicability of these features and functions to your device being used.

Topic **Page**

18.1 Overview **626**
18.2 Module Operation **628**
18.3 Example **638**
18.4 CRC Control Registers **641**

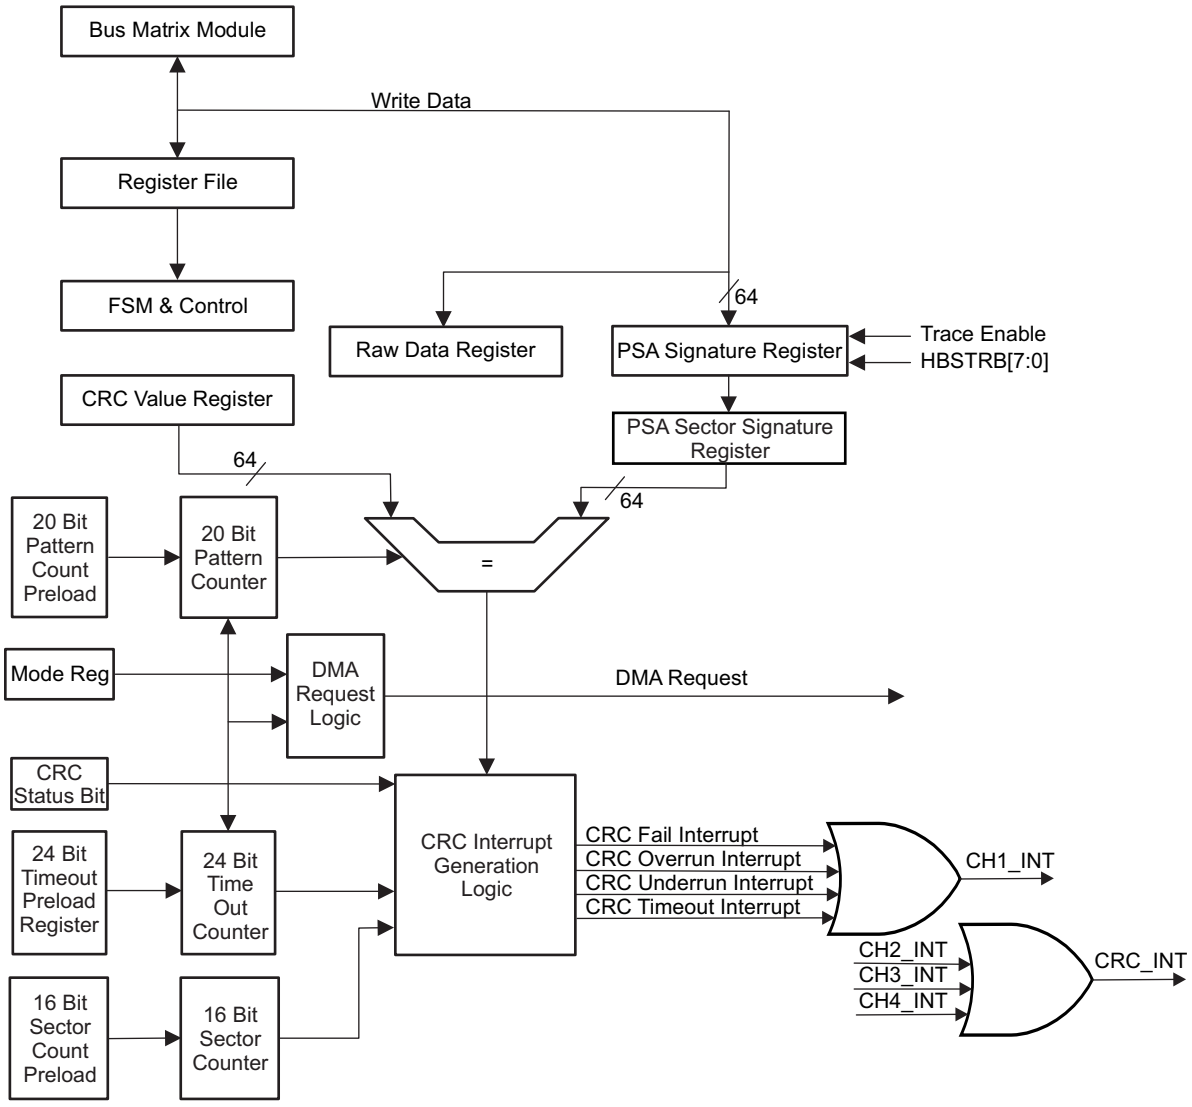
Copyright © 2018, Texas Instruments Incorporated

18.1 Overview

The CRC controller is a module that is used to perform CRC (Cyclic Redundancy Check) to verify the integrity of memory system. A signature representing the contents of the memory is obtained when the contents of the memory are read into CRC controller. The responsibility of CRC controller is to calculate the signature for a set of data and then compare the calculated signature value against a pre-determined good signature value. CRC controller supports two channels to perform CRC calculation on multiple memories in parallel and can be used on any memory system.

18.1.1 Features

The CRC controller offers:



- Two channels to perform background signature verification on any memory sub-system.
- Data compression on 8, 16, 32, and 64 bit data size.
- Maximum-length PSA (Parallel Signature Analysis) register constructed based on 64 bit primitive polynomial.
- Each channel has a CRC Value Register that contains the pre-determined CRC value.
- Use timed base event trigger from timer to initiate DMA data transfer.
- Programmable 20-bit pattern counter per channel to count the number of data patterns for compression.
- Three modes of operation. Auto, Semi-CPU and Full-CPU.
- For each channel, CRC can be performed either by CRC Controller or by CPU.
- Automatically perform signature verification without CPU intervention in AUTO mode.
- Generate interrupt to CPU in Semi-CPU mode to allow CPU to perform signature verification itself.
- Generate CRC fail interrupt in AUTO mode if signature verification fails.
- Generate Timeout interrupt if CRC is not performed within the time limit.
- Generate DMA request per channel to initiate CRC value transfer.

18.1.2 Block Diagram

Figure 18-1 shows a block diagram of the CRC controller.

Figure 18-1. CRC Controller Block Diagram For One Channel

Copyright © 2018, Texas Instruments Incorporated

18.2 Module Operation

18.2.1 General Operation

There are two channels in CRC controller and for each channel there is a memory mapped PSA (Parallel Signature Analysis) Signature Register and a memory mapped CRC (Cyclic Redundancy Check) Value register. A memory can be organized into multiple sectors with each sector consisting of multiple data patterns. A data pattern can be 8-, 16-, 32-, or 64-bit data. CRC module performs the signature calculation and compares the signature to a pre-determined value. The PSA Signature Register compresses an incoming data pattern into a signature when it is written. When one sector of data patterns are written into PSA Signature Register, a final signature corresponding to the sector is obtained. CRC Value Register stores the pre-determined signature corresponding to one sector of data patterns. The calculated signature and the pre-determined signature are then compared to each other for signature verification. To minimize CPU's involvement, data patterns transfer can be carried out at the background of CPU using DMA controller. DMA is setup to transfer data from memory from which the contents to be verified to the memory mapped PSA Signature Register. When DMA transfers data to the memory mapped PSA Signature Register, a signature is generated. A programmable 20-bit data pattern counter is used for each channel to define the number of data patterns to calculate for each sector. Signature verification can be performed automatically by CRC controller in AUTO mode or by CPU itself in Semi-CPU or Full-CPU mode. In AUTO mode, a self sustained CRC signature calculation can be achieved without any CPU intervention.

18.2.2 CRC Modes of Operation

CRC Controller can operate in AUTO, Semi-CPU, and Full-CPU modes.

18.2.2.1 AUTO Mode

In AUTO mode, CRC Controller in conjunction with DMA controller can perform CRC totally without CPU intervention. A sustained transfer of data to both the PSA Signature Register and CRC Value Register are performed in the background of CPU. When a mismatch is detected, an interrupt is generated to CPU. A 16 bit current sector ID register is provided to identify which sector causes a CRC failure.

18.2.2.2 Semi-CPU Mode

In Semi-CPU mode, DMA controller is also utilized to perform data patterns transfer to PSA Signature Register. Instead of performing signature verification automatically, the CRC controller generates an compression complete interrupt to CPU after each sector is compressed. Upon responding to the interrupt the CPU performs the signature verification by reading the calculated signature stored at the PSA Sector Signature Register and compare it to a pre-determined CRC value.

18.2.2.3 Full CPU Mode

In Full-CPU mode, the CPU does the data patterns transfer and signature verification all by itself. When CPU has enough throughput, it can perform data patterns transfer by reading data from the memory system to the PSA Signature Register. After certain number of data patterns are compressed, the CPU can read from the PSA Signature Register and compare the calculated signature to the pre-determined CRC signature value. In Full-CPU mode, neither interrupt nor DMA request is generated. All counters are also disabled.

18.2.3 PSA Signature Register

The 64-bit PSA Signature Register is based on the primitive polynomial (as in the following equation) to produce the maximum length LFSR (Linear Feedback Shift Register), as shown in Figure 18-2.

$$f(x) = x^{64} + x^4 + x^3 + x + 1 \quad (25)$$

Figure 18-2. Linear Feedback Shift Register (LFSR)

The serial implementation of LFSF has a limitation that, it requires ‘n’ clock cycles to calculate the CRC values for an ‘n’ bit data stream. The idea is to produce the same CRC value operating on a multi-bit data stream, as would occur if the CRC were computed one bit at a time over the whole data stream. The algorithm involves looping to simulate the shifting, and concatenating strings to build the equations after ‘n’ shift.

The parallel CRC calculation based on the polynomial can be illustrated in the following HDL code:

```
for i in 63 to 0 loop
   NEXT_CRC_VAL(0) := CRC_VAL(63) xor DATA(i);
     for j in 1 to 63 loop
       case j is
          when 1|3|4 =>
               NEXT_CRC_VAL(j) :=
                   CRC_VAL(j - 1) xor CRC_VAL(63) xor DATA(i);
          when others =>
               NEXT_CRC_VAL(j) := CRC_VAL(j - 1);
       end case;
     end loop;
   CRC_VAL := NEXT_CRC_VAL;
end loop;
```

NOTE: 1) The inner loop is to calculate the next value of each shift register bit after one cycle

2) The outer loop is to simulate 64 cycles of shifting. The equation for each shift register bit is thus built before it is compressed into the shift register.

3) MSB of the DATA is shifted in first

There is one PSA Signature Register per CRC channel. PSA Signature Register can be both read and written. When it is written, it can either compress the data or just capture the data depending on the state of CHx_MODE bits. If CHx_MODE=Data Capture, a seed value can be planted in the PSA Signature Register without compression. Other modes other than Data Capture will result with the data compressed by PSA Signature Register when it is written. Each channel can be planted with different seed value before compression starts. When PSA Signature Register is read, it gives the calculated signature.

CRC Controller should be used in conjunction with the on chip DMA controller to produce optimal system performance. The incoming data pattern to PSA Signature Register is typically initiated by the DMA master. When DMA is properly setup, it would read data from the pre-determined memory system and write them to the memory mapped PSA Signature Register. Each time PSA Signature Register is written a signature is generated. CPU itself can also perform data transfer by reading from the memory system and perform write operation to PSA Signature Register if CPU has enough throughput to handle data patterns transfer.

Copyright © 2018, Texas Instruments Incorporated

After system reset and when AUTO mode is enabled, CRC Controller automatically generates a DMA request to request the pre-determined CRC value corresponding to the first sector of memory to be checked.

In AUTO mode, when one sector of data patterns is compressed, the signature stored at the PSA Signature Register is first copied to the PSA Sector Signature Register and PSA Signature Register is then cleared out to all zeros. An automatic signature verification is then performed by comparing the signature stored at the PSA Sector Signature Register to the CRC Value Register. After the comparison the CRC Controller can generate a DMA request. Upon receiving the DMA request the DMA controller will update the CRC Value Register by transferring the next pre-determined signature value associated with the next sector of memory system. If the signature verification fails then CRC Controller can generate a CRC fail interrupt.

In Full-CPU mode, no DMA request and interrupt are generated at all. The number of data patterns to be compressed is determined by CPU itself. Full-CPU mode is useful when DMA controller is not available to perform background data patterns transfer. The OS can periodically generate a software interrupt to CPU and use CPU to accomplish data transfer and signature verification.

CRC Controller supports doubleword, word, half word and byte access to the PSA Signature Register. During a non-doubleword write access, all unwritten byte lanes are padded with zero's before compression. Note that comparison between PSA Sector Signature Register and CRC Value Register is always in 64 bit because a compressed value is always expressed in 64 bit.

There is a software reset per channel for PSA Signature Register. When set, the PSA Signature Register is reset to all zeros.

PSA Signature Register is reset to zero under the following conditions:

- System reset
- PSA Software reset
- One sector of data patterns are compressed

18.2.4 PSA Sector Signature Register

After one sector of data is compressed, the final resulting signature calculated by PSA Signature Register is transferred to the PSA Sector Signature Register. PSA Signature Register is a read only register. During Semi-CPU mode, the host CPU should read from the PSA Sector Signature Register instead of reading from PSA Signature Register for signature verification to avoid data coherency issue. The PSA Signature Register can be updated with new signature before the host CPU is able to retrieve it.

In Semi-CPU mode, no DMA request is generated. When one sector of data patterns is compressed, CRC controller first generates a compression complete interrupt. Responding to the interrupt, CPU will in the ISR read the PSA Sector Signature Register and compare it to the known good signature or write the signature value to another memory location to build a signature file. In Semi-CPU mode, CPU must perform the signature verification in a manner to prevent any overrun condition. The overrun condition occurs when the compression complete interrupt is generated after one sector of data patterns is compressed and CPU has not read from the PSA Sector Signature Register to perform necessary signature verification before PSA Sector Signature Register is overridden with a new value. An overrun interrupt can be enable to generate when overrun condition occurs. During Semi-CPU mode, the host CPU should read from the PSA Sector Signature Register instead of reading from PSA Signature Register for signature verification to avoid data coherency issue. The PSA Signature Register can be updated with new signature before the host CPU is able to retrieve it.

Copyright © 2018, Texas Instruments Incorporated

18.2.5 CRC Value Register

Associated with each channel there is a CRC Value Register. The CRC Value Register stores the pre-determined CRC value. After one sector of data patterns is compressed by PSA Signature Register, CRC Controller can automatically compare the resulting signature stored at the PSA Sector Signature Register with the pre-determined value stored at the CRC Value Register if AUTO mode is enabled. If the signature verification fails, CRC Controller can be enabled to generate an CRC fail interrupt. When the channel is set up for Semi-CPU mode, CRC controller first generates a compression complete interrupt to CPU. Upon servicing the interrupt, CPU will then read the PSA Sector Signature Register and then read the corresponding CRC value stored at another location and compare them. CPU should not read from the CRC Value Register during Semi-CPU or Full-CPU mode because the CRC Value Register is not updated during these two modes.

In AUTO mode, for first sector's signature, DMA request is generated when mode is programmed to AUTO. For subsequent sectors, DMA request is generated after each sector is compressed. Responding to the DMA request, DMA controller reloads the CRC Value Register for the next sector of memory system to be checked.

When CRC Value Register is updated with a new CRC value, an internal flag is set to indicate that CRC Value Register contains the most current value. This flag is cleared when CRC comparison is performed. Each time at the end of the final data pattern compression of a sector, CRC Controller first checks to see if the corresponding CRC Value Register has the most current CRC value stored in it by polling the flag. If the flag is set then the CRC comparison can be performed. If the flag is not set then it means the CRC Value Register contains stale information. A CRC underrun interrupt is generated. When an underrun condition is detected, signature verification is not performed.

CRC Controller supports doubleword, word, half word and byte access to the CRC Value Register. As noted before comparison between PSA Sector Signature Register and CRC Value Register during AUTO mode is carried out in 64 bit.

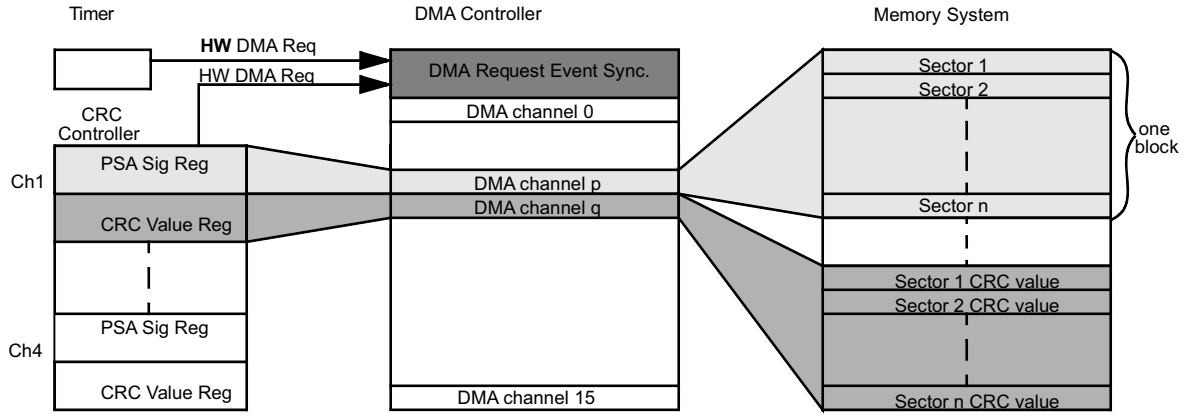
18.2.6 Raw Data Register

The raw or un-compressed data written to the PSA Signature Register is also saved in the Raw Data Register. This register is read only.

18.2.7 Example DMA Controller Setup

DMA controller needs to be setup properly in either either AUTO or Semi-CPU mode as DMA controller is used to transfer data patterns. Hardware or a combination of hardware and software DMA triggering are supported.

18.2.7.1 AUTO Mode Using Hardware Timer Trigger



There are two DMA channels associated with each CRC channel when in AUTO mode. One DMA channel is setup to transfer data patterns from the source memory to the PSA Signature Register. The second DMA channel is setup to transfer the pre-determined signature to the CRC Value Register. The trigger source for the first DMA channel can be either by hardware or by software. As illustrated in Figure 18-3 a timer can be used to trigger a DMA request to initiate transfer from the source memory system to PSA Signature Register. In AUTO mode, CRC Controller also generates DMA request after one sector of data patterns is compressed to initiate transfer of the next CRC value corresponding to the next sector of memory. Thus a new CRC value is always updated in the CRC Value Register by DMA synchronized to each sector of memory.

A block of memory system is usually divided into many sectors. All sectors are the same size. The sector size is programmed in the CRC_PCOUNT_REGx and the number of sectors in one block is programmed in the CRC_SCOUNT_REGx of the respective channel. CRC_PCOUNT_REGx multiplies CRC_SCOUNT_REGx and multiplies transfer size of each data pattern should give the total block size in number of bytes.

Copyright © 2018, Texas Instruments Incorporated

The total size of the memory system to be examined is also programmed in the respective transfer count register inside DMA module. The DMA transfer count register is divided into two parts. They are element count and frame count. Note that an HW DMA request can be programmed to trigger either one frame or one entire block transfer. In Figure 18-3, an HW DMA request from a timer is used as a trigger source to initiate DMA transfer. If all four CRC channels are active in AUTO mode then a total of four DMA requests would be generated by CRC Controller.

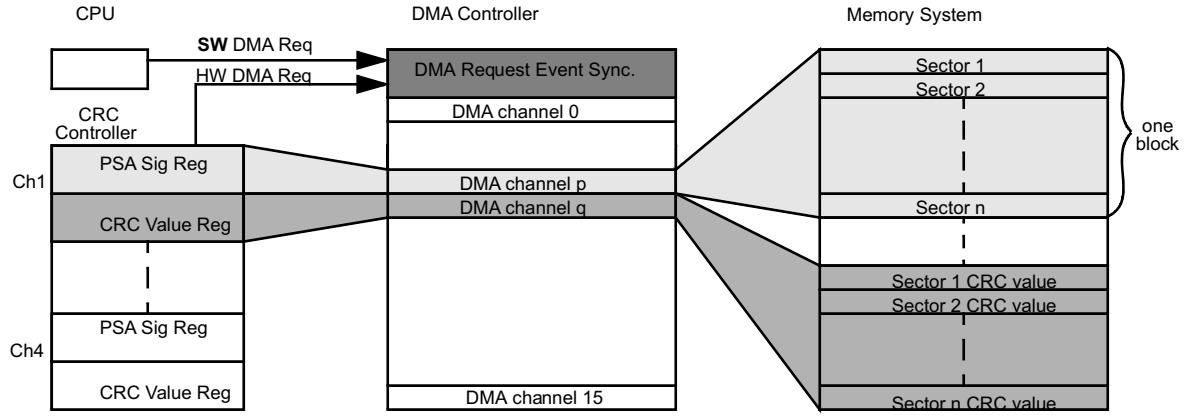


Figure 18-3. AUTO Mode Using Hardware Timer Trigger

18.2.7.2 AUTO Mode Using Software Trigger

The data patterns transfer can also be initiated by software. CPU can generate a software DMA request to activate the DMA channel to transfer data patterns from source memory system to the PSA Signature Register. To generate a software DMA request CPU needs to set the corresponding DMA channel in the DMA software trigger register. Note that just one software DMA request from CPU is enough to complete the entire data patterns transfer for all sectors. See Figure 18-4 for an illustration.

Figure 18-4. AUTO Mode With Software CPU Trigger

Copyright © 2018, Texas Instruments Incorporated

18.2.7.3 Semi-CPU Mode Using Hardware Timer Trigger

During semi-CPU mode, no DMA request is generated by CRC controller. Therefore, no DMA channel is allocated to update CRC Value Register. CPU should not read from CRC Value Register in semi-CPU mode as it contains stale value. Note that no signature verification is performed at all during this mode. Similar to AUTO mode, either by hardware or by software DMA request can be used as a trigger for data patterns transfer. Figure 18-5 illustrates the DMA setup using semi-CPU mode with hardware timer trigger.

Figure 18-5. Semi-CPU Mode With Hardware Timer Trigger

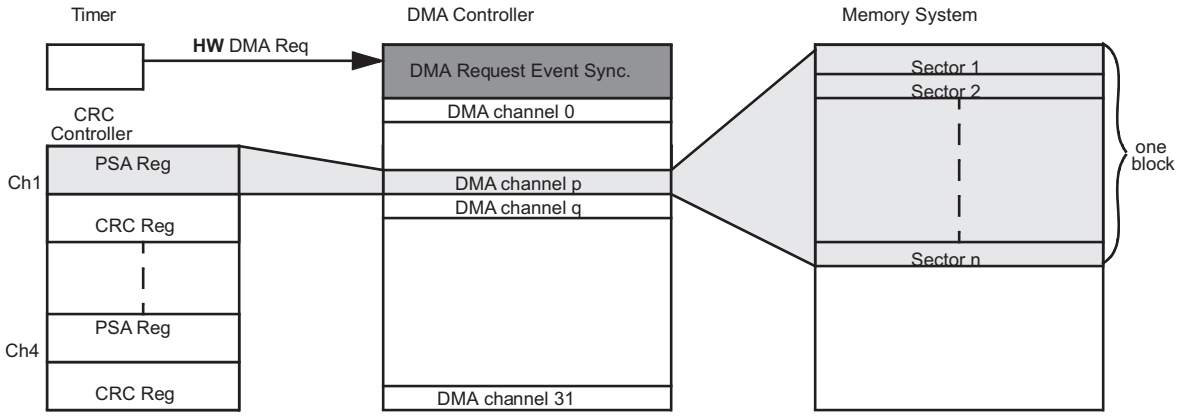

Table 18-1. CRC Modes in Which DMA Request and Counter Logic are Active or Inactive

Mode	DMA Request	Pattern Counter	Sector Counter	Timeout Counter
AUTO	Active	Active	Active	Active
Semi-CPU	Inactive	Active	Active	Active
Full-CPU	Inactive	Inactive	Inactive	Inactive

18.2.8 Pattern Count Register

There is a 20-bit data pattern counter for every CRC channel. The data pattern counter is a down counter and can be pre-loaded with a programmable value stored in the Pattern Count Register. When the data pattern counter reaches zero, a compression complete interrupt is generated in Semi-CPU mode and an automatic signature verification is performed in AUTO mode. In AUTO only, DMA request is generated to trigger the DMA controller to update the CRC Value Register.

NOTE: The data pattern count should be divisible by the total transfer count as programmed in DMA controller. The total transfer count is the product of element count and frame count.

18.2.9 Sector Count Register/Current Sector Register

Each channel contains a 16 bit sector counter. The sector count register stores the number of sectors. Sector counter is a free running counter and is incremented by one each time when one sector of data patterns is compressed. When the signature verification fails, the current value stored in the sector counter is saved into current sector register. If signature verification fails, CPU can read from the current sector register to identify the sector which causes the CRC mismatch. To aid and facilitate the CPU in determining the cause of a CRC failure, it is advisable to use the following equation during CRC and DMA setup:

CRC Pattern Count × CRC Sector Count = DMA Element Count × DMA Frame Count

Copyright © 2018, Texas Instruments Incorporated

The current sector register is frozen from being updated until both the current sector register is read and CRC fail status bit is cleared by CPU. If CPU does not respond to the CRC failure in a timely manner before another sector produces a signature verification failure, the current sector register is not updated with the new sector number. An overrun interrupt is generate instead. If current sector register is already frozen with an erroneous sector and emulation is entered with SUSPEND signal goes to high then the register still remains frozen even it is read.

In Semi-CPU mode, the current sector register is used to indicate the sector for which the compression complete has last happened.

The current sector register is reset when the PSA software reset is enabled.

NOTE: Both data pattern count and sector count registers must be greater than or equal to one for the counters to count. After reset, pattern count and sector count registers default to zero and the associated counters are inactive.

18.2.10 Interrupt

The CRC controller generates several types of interrupts per channel. Associated with each interrupt, there is an interrupt enable bit. No interrupt is generated in Full-CPU mode.

- Compression complete interrupt
- CRC fail interrupt
- Overrun interrupt
- Underrun interrupt
- Timeout interrupt

Table 18-2. Modes in Which Interrupt Condition Can Occur

	AUTO	Semi-CPU	Full-CPU
Compression Complete	no	yes	no
CRC Fail	yes	no	no
Overrun	yes	yes	no
Underrun	yes	no	no
Timeout	yes	yes	no

18.2.10.1 Compression Complete Interrupt

Compression complete interrupt is generated in Semi-CPU mode only. When the data pattern counter reaches zero, the compression complete flag is set and the interrupt is generated.

18.2.10.2 CRC Fail Interrupt

CRC fail interrupt is generated in AUTO mode only. When the signature verification fails, the CRC fail flag is set,. CPU should take action to address the fail condition and clear the CRC fail flag after it resolves the CRC mismatch.

18.2.10.3 Overrun Interrupt

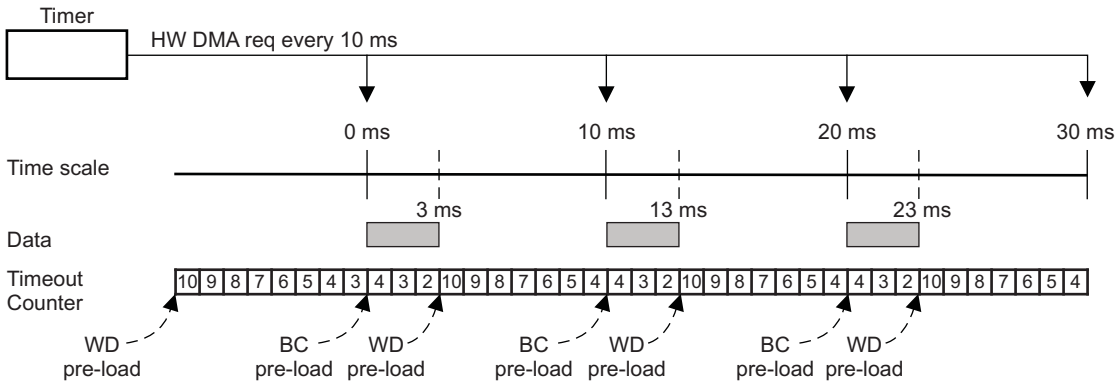
Overrun interrupt is generated in either AUTO or Semi-CPU mode. During AUTO mode, if a CRC fail is detected then the current sector number is recorded in the current sector register. If CRC fail status bit is not cleared and current sector register is not read by the host CPU before another CRC fail is detected for another sector then an overrun interrupt is generated. During Semi-CPU mode, when the data pattern counter finishes counting, it generates a compression complete interrupt. At the same time the signature is copied into the PSA Sector Signature Register. If the host CPU does not read the signature from PSA Sector Signature Register before it is updated again with a new signature value then an overrun interrupt is generated.

Copyright © 2018, Texas Instruments Incorporated

18.2.10.4 Underrun Interrupt

Underrun interrupt only occurs in AUTO mode. The interrupt is generated when the CRC Value Register is not updated with the corresponding signature when the data pattern counter finishes counting. During AUTO mode, CRC Controller generates DMA request to update CRC Value Register in synchronization to the corresponding sector of the memory. Signature verification is also performed if underrun condition is detected. And CRC fail interrupt is generated at the same time as the underrun interrupt.

18.2.10.5 Timeout Interrupt



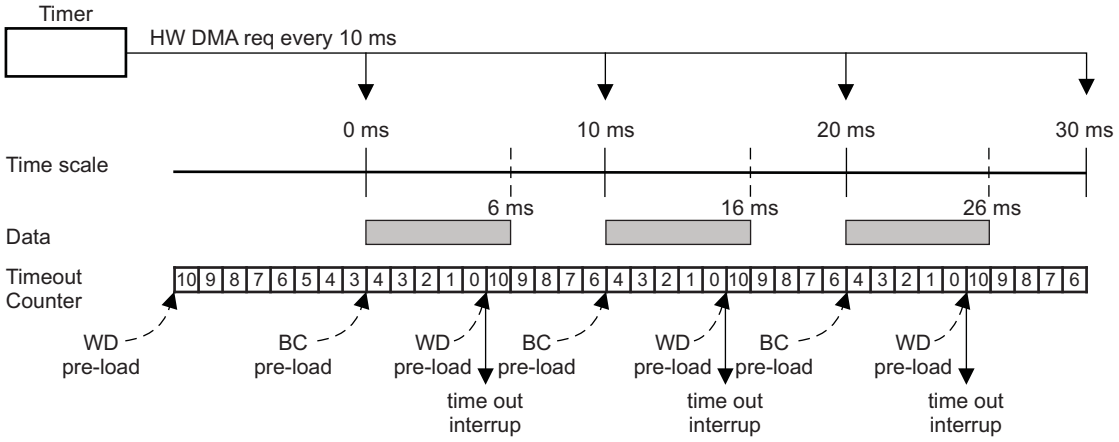
To ensure that the memory system is examined within a pre-defined time frame and no loss of incoming data there is a 24 bit timeout counter per CRC channel. The 24 bit timeout down counter can be pre-loaded with two different pre-load values, watchdog timeout pre-load value (CRC_WDTOPLDx) and block complete timeout pre-load value (CRC_BCTOPLDx). The timeout counter is clocked by a prescaler clock which is permanently running at division 64 of HCLK clock.

First pattern of data must be transferred by the DMA before the timeout counter expires, Watchdog timeout pre-load register (CRC_WDTOPLDx) is used as timeout counter. Block complete timeout pre-load register (CRC_BCTOPLDx) is used to check if one complete block of data patterns are compressed within a specific time frame. The timeout counter is first pre-loaded with CRC_WDTOPLDx after either AUTO or Semi-CPU mode is selected and starts to down count. If the timeout counter expires before DMA transfers any data pattern to PSA Signature Register then a timeout interrupt is generated. An incoming data pattern before the timeout counter expires will automatically pre-load the timeout counter with CRC_BCTOPLDx the block complete timeout pre-load value.

Block complete timeout pre-load value is used to check it one block of data patterns are compressed within a given time limit. If the timeout counter pre-loaded with CRC_BCTOPLDx value expires before one block of data patterns are compressed a timeout interrupt is generated. When one block (pattern count x sector count) of data patterns are compressed before the counter has expired, the counter is pre-loaded with CRC_WDTOPLDx value again. If the timeout counter is pre-loaded with zero then the counter is disable and no timeout interrupt is generated.

In Figure 18-6, a timer generates DMA request every 10ms to trigger one block (pattern count x sector count) transfer. Since we want to make sure that DMA does start to transfer a block every 10 ms we would set the first pre-load value to 10ms in CRC_WDTOPLDx. We also want to make sure that one block of data patterns are compressed within 4ms. With such a requirement, we would set the second pre-load value to 4ms in CRC_BCTOPLDx register.

Figure 18-6. Timeout Example 1



WD pre-load = watchdog timeout pre-load (CRC_WDTOPLDx)
BC pre-load = block complete timeout pre-load (CRC_BCTOPLDx)

Note: No timeout interrupt is generated in this example since each block of data patterns are compressed in 3 ms and DMA does initiate a block transfer every 10 ms.

Copyright © 2018, Texas Instruments Incorporated

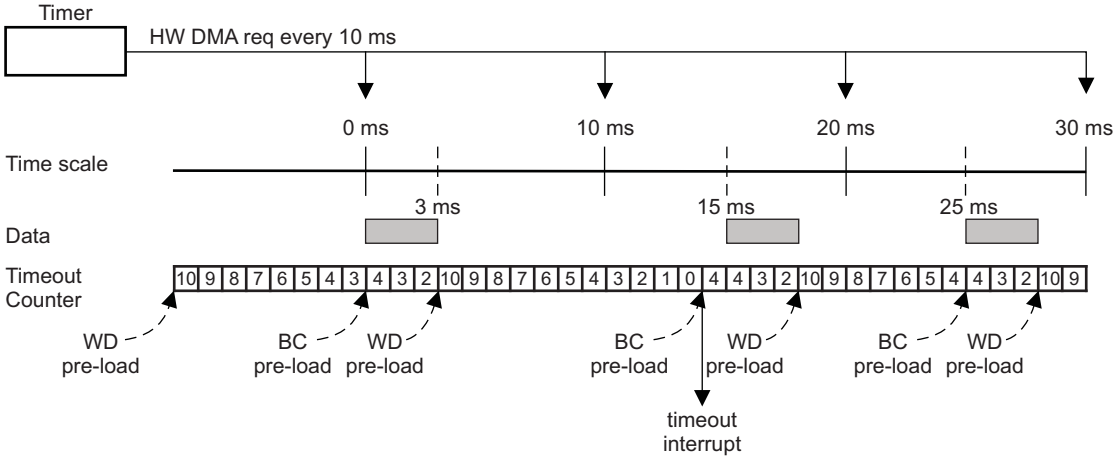


Figure 18-7. Timeout Example 2

WD pre-load = watchdog timeout pre-load (CRC_WDTOPLDx)
BC pre-load = block complete timeout pre-load (CRC_BCTOPLDx)

Note: Timeout interrupt is generated in this example since each block of data patterns are compressed in 6 ms and this is out of the 4ms time frame.

Figure 18-8. Timeout Example 3

WD pre-load = watchdog timeout pre-load (CRC_WDTOPLDx)
BC pre-load = block complete timeout pre-load (CRC_BCTOPLDx)

Note: Timeout interrupt is generated in this example since DMA can not transfer the second block of data within 10ms time limit and the reason may be that DMA is set up in fixed priority scheme and DMA is serving other higher priority channels at the time before it can service the timer request.

Copyright © 2018, Texas Instruments Incorporated

18.2.10.6 Interrupt Offset Register

CRC Controller only generates one interrupt request to interrupt manager. A interrupt offset register is provided to indicate the source of the pending interrupt with highest priority. Table 18-3 shows the offset interrupt vector address of each interrupt condition in an ascending order of priority.

Table 18-3. Interrupt Offset Mapping

Offset Value	Interrupt Condition
0	Phantom
1h	Ch1 CRC Fail
2h	Ch2 CRC Fail
3h-8h	Reserved
9h	Ch1 Compression Complete
Ah	Ch2 Compression Complete
Bh-10h	Reserved
11h	Ch1 Overrun
12h	Ch2 Overrun
13h-18h	Reserved
19h	Ch1 Underrun
1Ah	Ch2 Underrun
1Bh-20h	Reserved
21h	Ch1 Timeout
22h	Ch2 Timeout
23h-24h	Reserved

18.2.10.7 Error Handling

When an interrupt is generated, host CPU should take appropriate actions to identify the source of error and restart the respective channel in DMA and CRC module. To restart a CRC channel, the user should perform the following steps in the ISR:

1. Write to software reset bit in CRC_CTRL register to reset the respective PSA Signature Register.
2. Reset the CHx_MODE bits to 00 in CRC_CTRL register as Data capture mode.
3. Set the CHx_MODE bits in CRC_CTRL register to desired new mode again.
4. Release software reset.

The host CPU should use byte write to restart each individual channel.

18.2.11 Power Down Mode

CRC module can be put into power down mode when the power down control bit PWDN is set. The module wakes up when the PWDN bit is cleared.

18.2.12 Emulation

A read access from a register in functional mode can sometimes trigger a certain internal event to follow. For example, reading an interrupt offset register triggers an event to clear the corresponding interrupt status flag. During emulation when SUSPEND signal is high, a read access from any register should only return the register contents to the bus and should not trigger or mask any event as it would have in functional mode. This is to prevent debugger from reading the interrupt offset register during refreshing screen and cause the corresponding interrupt status flag to get cleared. Timeout counters are stopped to generate timeout interrupts in emulation mode. No Peripheral Master bus error should be generated if reading from the unimplemented locations.

Copyright © 2018, Texas Instruments Incorporated

18.2.13 Peripheral Bus Interface

CRC is a Peripheral slave module. The register interface is similar to other peripheral modules. CRC supports following features:

- Different sizes of burst operation.
- Aligned and unaligned accesses.
- Abort is generated for any illegal address accesses.

18.3 Example

This section illustrates several of the ways in which the CRC Controller can be utilized to perform CRC.

18.3.1 Example: Auto Mode Using Time Based Event Triggering

A large memory area with 2Mbyte (256k doubleword) is to be checked in the background of CPU. CRC is to be performed every 1K byte (128 doubleword). Therefore there should be 2048 pre-recorded CRC values. For illustration purpose, we map channel 1 CRC Value Register to DMA channel 1 and channel 1 PSA Signature Register to DMA channel 2. Assume all DMA transfers are carried out in 64-bit transfer size.

18.3.1.1 DMA Setup

- Set up DMA channel 1 with the starting address from which the pre-determined CRC values are stored. Set up the destination address to the memory mapped channel 1 CRC Value Register. Put the source address at post increment addressing mode and put the destination address at constant addressing mode. Use ***hardware*** DMA request for channel 1 to trigger a ***frame*** transfer.
- Set up DMA channel 2 with the source address from which the contents of memory to be verified. Set up the destination address to the memory mapped channel 1 PSA Signature Register. Program the element transfer count to 128 and the frame transfer count to 2048. Put the source address at post increment addressing mode and put the destination address at constant address mode. Use ***hardware*** DMA request for channel 2 to trigger an entire ***block*** transfer.

18.3.1.2 Timer Setup

The timer can be any general purpose timer which is capable of generating a time-based DMA request.

- Set up timer to generate DMA request associated with DMA channel 2. For example, an OS can set up the timer to generate a DMA request every 10ms.

Copyright © 2018, Texas Instruments Incorporated

18.3.1.3 CRC Setup

- Program the pattern count to 128.
- Program the sector count to 2048.
- For example, we want the entire 2Mbytes to be compressed within 5ms. We can program the block complete timeout pre-load (CRC_BCTOPLDx) value to 15625 (5 ms / (1 HCLK period × 64)) if CRC is operating at 200 MHz.
- Enable AUTO mode and all interrupts.

After AUTO mode is selected, CRC Controller automatically generates a DMA request on channel 1. Around the same time the timer module also generates a DMA request on DMA channel 2. When the first incoming data pattern arrives at the PSA Signature Register, the CRC Controller will compress it. After some time, the DMA controller would update the CRC Value Register with a pre-determined value matching the calculated signature for the first sector of 128 64 bit data patterns. After one sector of data patterns are compressed, the CRC Controller generate a CRC fail interrupt if signature stored at the PSA Sector Signature Register does not match the CRC Value Register. CRC Controller generates a DMA request on DMA channel 1 when one sector of data patterns are compressed. This routine will continue until the entire 2Mbyte are consumed. If the timeout counter reached zero before the entire 2Mbytes are compressed a timeout interrupt is generated. After 2MBytes are transferred, the DMA can generate an interrupt to CPU. The entire operation will continue again when DMA responds to the DMA request from both the timer and CRC Controller. The CRC is performed totally without any CPU intervention.

18.3.2 Example: Auto Mode Without Using Time Based Triggering

A small but highly secured memory area with 1kbytes is to be checked in the background of CPU. CRC is to be performed every 1Kbytes. Therefore there is only one pre-recorded CRC value. For illustration purpose, we map channel 1 CRC Value Register to DMA channel 1 and channel 1 PSA Signature Register to DMA channel 2. Assume all transfers carried out by DMA are in 64 bit transfer size.

18.3.2.1 DMA Setup

- Set up DMA channel 1 with the source address from which the pre-determined CRC value is stored. Set up the destination address to the memory mapped channel 1 CRC Value Register. Put the source address at constant addressing mode and put the destination address at constant addressing mode. Use ***hardware*** DMA request for channel 1.
- Set up DMA channel 2 with the source address from which the memory area to be verified. Set up the destination address to the memory mapped channel 1 PSA Signature Register. Program the element transfer count to 128 and the frame transfer count to 1. Put the source address at post increment addressing mode and put the destination address at constant address mode. Generate a ***software*** DMA request on channel 2 after CRC has completed its setup. Enable autoinitiation for DMA channel 2.

18.3.2.2 CRC Setup

- Program the pattern count to 128.
- Program the sector count to 1.
- Leaving the timeout count register with the reset value of zero means no timeout interrupt is generated.
- Enable AUTO mode and all interrupts.

After AUTO mode is selected, the CRC Controller automatically generates a DMA request on channel 1. At the same time the CPU generates a ***software*** DMA request on DMA channel 2. When the first incoming data pattern arrives at the PSA Signature Register, the CRC Controller will compress it. After some time, the DMA controller would update the CRC Value Register with a pre-determined value matching the calculated signature for the first sector of 128 64 bit data patterns. After one sector of data patterns are compressed, the CRC Controller generates a CRC fail interrupt if signature stored at the PSA Sector Signature Register does not match the CRC Value Register. CRC Controller generates a DMA request on DMA channel 1 again after one sector is compressed. After 1kbytes are transferred, the DMA can generate an interrupt to CPU. Responding to the DMA interrupt CPU can restart the CRC routine by generating a software DMA request onto channel 2 again.

Copyright © 2018, Texas Instruments Incorporated

18.3.3 Example: Semi-CPU Mode

If DMA controller is available in a system, the CRC module can also operate in semi-CPU mode. This means that CPU can still make use of the DMA to perform data patterns transfer to CRC controller in the background. The difference between semi-CPU mode and AUTO mode is that CRC controller does not automatically perform the signature verification. CRC controllers generates a compression complete interrupt to CPU when the one sector of data patterns are compressed. CPU needs to perform the signature verification itself.

A memory area with 2Mbyte is to be verified with the help of the CPU. CRC operation is to be performed every 1K byte. Since there are 2Mbyte (256k doublewords) of memory to be check and we want to perform a CRC every 1Kbyte (128 doublewords) and therefore there should be 2048 pre-recorded CRC values. In Semi-CPU mode, the CRC Value Register is not updated and contains indeterminate data.

18.3.3.1 DMA Setup

Set up DMA channel 1 with the source address from which the memory area to be verified are mapped. Set up the destination address to the memory mapped channel 1 PSA Signature Register. Put the starting address at post increment addressing mode and put the destination address at constant address mode. Use hardware DMA request to trigger an entire block transfer for channel 1. Disable autoinitiation for DMA channel 1.

18.3.3.2 Timer Setup

The timer can be any general purpose timer which is capable of generating a time based DMA request.

Set up timer to generate DMA request associated with DMA channel 1. For example, an OS can set up the timer to generate a DMA request every 10ms.

18.3.3.3 CRC Setup

- Program the pattern count to 128.
- Program the sector count to 2048.
- For example, we want the entire 2Mbytes to be compressed within 5ms. We can program the block complete timeout pre-load value to 15625 (5 ms / (1 HCLK period × 64)) if CRC is operating at 200 MHz.
- Enable Semi-CPU mode and enable all interrupts.

The timer module first generates a DMA request on DMA channel 1 when it is enabled. When the first incoming data pattern arrives at the PSA Signature Register, the CRC controller will compress it. After one sector of data patterns are compressed, the CRC controller generate a compression complete interrupt. Upon responding to the interrupt the CPU would read from the PSA Sector Signature Register. It is up to the CPU on how to deal with the PSA value just read. It can compare it to a known signature value or it can write it to another memory location to build a signature file or even transfer the signature out of the device via SCI or SPI. This routine will continue until the entire 2Mbyte are consumed. The latency of the interrupt response from CPU can cause overrun condition. If CPU does not read from PSA Sector Signature Register before the PSA value is overridden with the signature of the next sector of memory, an overrun interrupt will be generated by CRC controller.

18.3.4 Example: Full-CPU Mode

In a system without the availability of DMA controller, the CRC routine can be operated by CPU provided the CPU has enough throughput. CPU needs to read from the memory area from which CRC is to be performed.

A memory area with 2Mbyte is to be checked with the help of the CPU. CRC verification is to be performed every 1K byte. In CPU mode, the CRC Value Register is not updated and contains indeterminate data.

Copyright © 2018, Texas Instruments Incorporated

18.3.4.1 CRC Setup

- All control registers can be left in their reset state. Only enable Full-CPU mode.

CPU itself reads from the memory and write the data to the PSA Signature Register inside CRC Controller. When the first incoming data pattern arrives at the PSA Signature Register, the CRC Controller will compress it. After ***2MBytes*** data patterns are compressed, CPU can read from the PSA Signature Register. It is up to the CPU on how to deal with the PSA signature value just read. It can compare it to a known signature value stored at another memory location.

18.4 CRC Control Registers

All registers are in word boundary. 64, 32, 16, and 8 bit write accesses are supported to all registers. The base address for the control registers is FE00 0000h for CRC1 and FB00 0000h for CRC2.

Table 18-4. CRC Control Registers

Offset	Acronym	Register Description	Section
0h	CRC_CTRL0	CRC Global Control Register	Section 18.4.1
8h	CRC_CTRL1	CRC Global Control Register 1	Section 18.4.2
10h	CRC_CTRL2	CRC Global Control Register 2	Section 18.4.3
18h	CRC_INTS	CRC Interrupt Enable Set Register	Section 18.4.4
20h	CRC_INTR	CRC Interrupt Enable Reset Register	Section 18.4.5
28h	CRC_STATUS	CRC Interrupt Status Register	Section 18.4.6
30h	CRC_INT_OFFS_ET_REG	CRC Interrupt Offset Register	Section 18.4.7
38h	CRC_BUSY	CRC Busy Register	Section 18.4.8
40h	CRC_PCOUNT_REG1	CRC Channel 1 Pattern Counter Preload Register	Section 18.4.9

Table 18-15. CRC Current Sector Register 1 (CRC_CURSEC_REG1) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
15-0	CRC_CURSEC1		Channel 1 Current Sector ID Register. In AUTO mode, this register contains the current sector number of which the signature verification fails. The sector counter is a free running up counter. When a sector fails, the erroneous sector number is logged into current sector ID register and the CRC fail interrupt is generated The sector ID register is frozen until it is read and the CRC fail status bit is cleared by CPU. While it is frozen, it does not capture another erroneous sector number. When this condition happens, an overrun interrupt is generated instead. Once the register is read and the CRC fail interrupt flag is cleared it can capture new erroneous sector number. In Semi-CPU mode, this register is used to indicate the sector number for which the compression complete has last happened.

15-0	CRC_CURSEC2		Channel 2 Current Sector ID Register. In AUTO mode, this register contains the current sector number of which the signature verification fails. The sector counter is a free running up counter. When a sector fails, the erroneous sector number is logged into current sector ID register and the CRC fail interrupt is generated The sector ID register is frozen until it is read and the CRC fail status bit is cleared by CPU. While it is frozen, it does not capture another erroneous sector number. When this condition happens, an overrun interrupt is generated instead. Once the register is read and the CRC fail interrupt flag is cleared it can capture new erroneous sector number. In Semi-CPU mode, this register is used to indicate the sector number for which the compression complete has last happened.

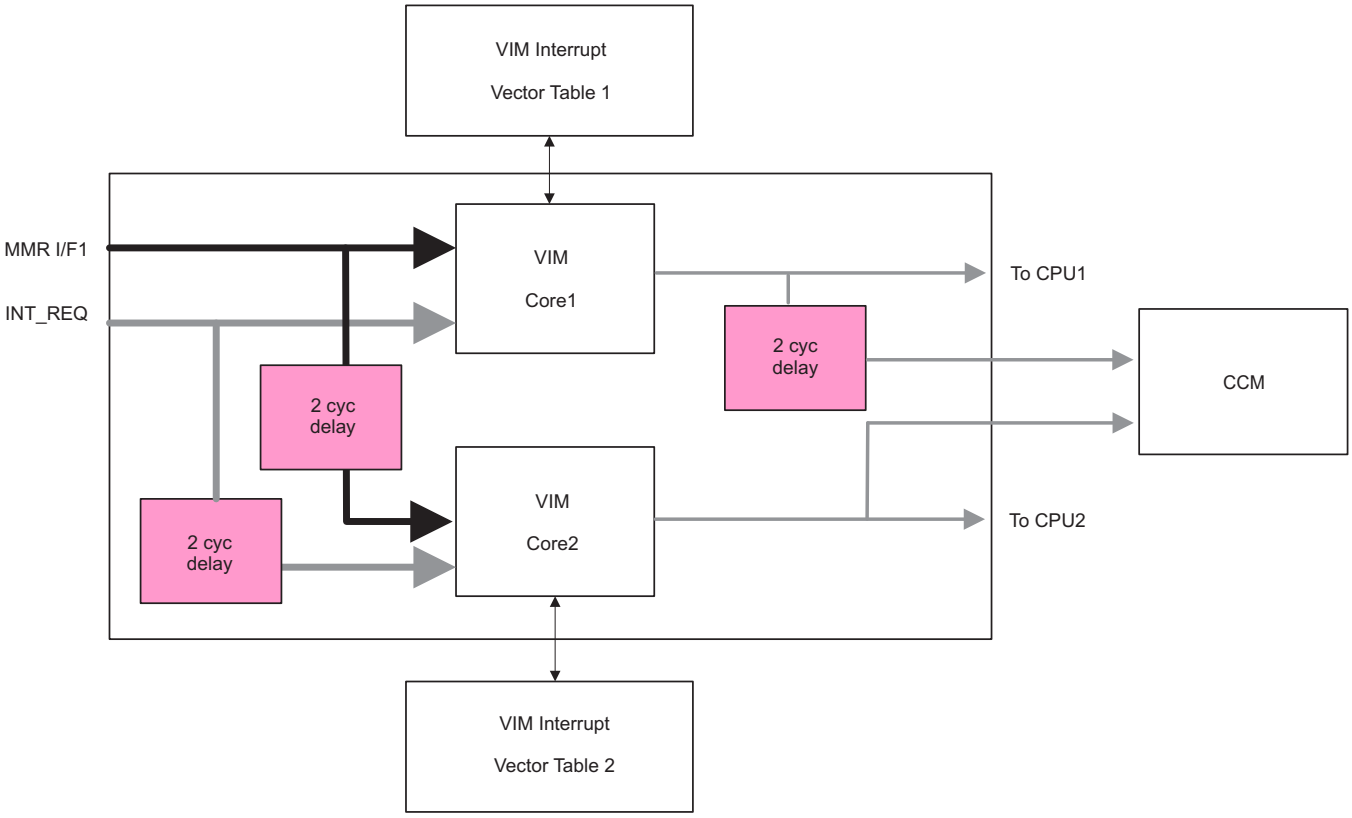
19.1 Overview

The vectored interrupt manager (VIM) provides hardware assistance for prioritizing and controlling the many interrupt sources present on a device. Interrupts are caused by events outside of the normal flow of program execution. Normally, these events require a timely response from the central processing unit (CPU); therefore, when an interrupt occurs, the CPU switches execution from the normal program flow to an interrupt service routine (ISR).

The VIM module has the following features:

- Dual VIM for safety
- Supports 127 interrupt channels, in both register vectored interrupt and hardware vectored interrupt mode.
  - Provides IRQ vector directly to the CPU VIC port
  - Provides FIQ/IRQ vector through registers
  - Provides programmable priority and enable for interrupt request lines
- Provides a direct hardware dispatch mechanism for fastest IRQ dispatch.
- Provides two software dispatch mechanisms for backward compatibility with earlier generation of TI processors.
  - Index interrupt
  - Register vectored interrupt
- ECC (Error Code Correction) protected vector interrupt table against soft errors.

Copyright © 2018, Texas Instruments Incorporated



19.2 Dual VIM for Safety

A block diagram of Dual VIM for safety support is shown in Figure 19-1. To reduce probability of common cause failure, the VIM module mimics the dual CPU scheme of two cycle delayed operation of the two cores. In this case, the MMR (Memory Mapped Register) interface to the second instance is delayed by two cycles. Similarly, the interrupt inputs are also delayed by two cycles to the second instance.

A separate set of “2 cycle” delayed versions of output ports for the CPU interrupt interface of the VIM1 are provided. These will be used as one of the compare inputs of CPU Compare Module (CCM). The CPU interface signals of VIM2 are used as second set of inputs of CCM.

VIM2 uses the same address space as that of VIM1. During LockStep mode, any write to VIM1 (including the Interrupt Vector Table) will be routed to VIM2 as well so that the secondary instance is programmed exactly as the first one and provide compare diagnostic support. Auto initialization of the VIM1 Interrupt Vector Table will result in VIM2 Interrupt Vector Table getting initialized as well in this mode. In this mode, reads from VIM will return only VIM1 data.VIM2 registers and Interrupt Vector Table cannot be read out in Locked mode.

Figure 19-1. Block Diagram of Dual VIM for Safety Support

19.3 Device Level Interrupt Management

A block diagram of device level interrupt handling is shown in Figure 19-2. When an event occurs within a peripheral, the peripheral makes an interrupt request to the VIM. Then, VIM prioritizes the requests from peripherals and provides the address of the highest interrupt service routine (ISR) to the CPU. Finally, CPU starts executing the ISR instructions from that address in the ISR. Section 19.3.1 through Section 19.3.3 provide additional details about these three steps.

Figure 19-2. Device Level Interrupt Block Diagram

19.3.1 Interrupt Generation at the Peripheral

Interrupt generation begins when an event occurs within a peripheral module. Some examples of interrupt-capable events are expiration of a counter within a timer module, receipt of a character in a communications module, and completion of a conversion in an analog-to-digital converter (ADC) module. Some device peripherals are capable of requesting interrupts on more than one interrupt request line.

Interrupts are not always generated when an event occurs; the peripheral must make an interrupt request to the VIM based on the event occurrence. Typically, the peripheral contains:

- An interrupt flag bit for each event to signify the event occurrence.
- An interrupt enable bit to control whether the event occurrence causes an interrupt request to the VIM.

Copyright © 2018, Texas Instruments Incorporated

19.3.2 Interrupt Handling at the CPU

The ARM CPU provides two vectors for interrupt requests—fast interrupt requests (FIQs) and normal interrupt requests (IRQs). FIQs are higher priority than IRQs, and FIQ interrupts may interrupt IRQ interrupts.

NOTE: The FIQ implemented in Cortex-R4F/R5F is Non-Maskable Fast Interrupts (NMFI). Once FIQ is enabled (by clearing F bit in CPSR), it can NOT be disabled by setting F bit in CPSR. Only a reset or an FIQ will be able to set the F bit in CPSR. By hardware, Non Maskable FIQ are not reentrant.

After reset (power reset or warm reset), both FIQ and IRQ are disabled. The CPU may enable these interrupt request channels individually within the CPSR (Current Program Status Register); CPSR bits 6 and 7 must be cleared to enable the FIQ (bit 6) and IRQ (bit 7) interrupt requests at the CPU. CPSR is writable in privilege mode only. Example 19-2 shows how to enable the IRQ and FIQ through CPSR.

When the CPU receives an interrupt request, the CPSR mode field changes to either FIQ or IRQ mode. When an IRQ interrupt is received, the CPU disables other IRQ interrupts by setting CPSR bit 7. When an FIQ interrupt is received, the CPU disables both IRQ and FIQ interrupts by setting CPSR bits 6 and 7.

A write of 1 to CPSR bit 7 disables the IRQ from CPU. However, a write of 1 to CPSR bit 6 leaves it unchanged. Example 19-2 also shows how to disable the IRQ through CPSR.

Copyright © 2018, Texas Instruments Incorporated

19.3.3 Software Interrupt Handling Options

The device supports three different possibilities for software to handle interrupts

1. Index interrupts mode (compatible with TMS470R1x legacy code)

   After the interrupt is received by the CPU, the CPU branches to 0x18 (IRQ) or 0x1C (FIQ) to execute the main ISR. The main ISR routine reads the offset register (IRQINDEX, FIQINDEX) to determine the source of the interrupt.

   This mode is compatible with the TMS470R1x (CIM) module and provides the same interrupt registers.

   This mode could be used if legacy code needs to be reused, porting it from the TMS470R1x family. However, imported software will not benefit from the VIM improvements.

   To port legacy software, the interrupt vector at 0x18 (IRQ) or 0x1C (FIQ) only needs to be a branch statement to a software interrupt table. The software interrupt table reads the pending interrupt from a vector offset register (FIQINDEX[7:0] for FIQ interrupts and IRQINDEX[7:0] for IRQ interrupts). All pending interrupts can be viewed in the INTREQ register. Example 19-4 shows how to respond to FIQ with short latency in this mode.

2. Register vectored interrupts (automatically provide vector address to application)

   Before enabling interrupts, the application software also has to initiate the interrupt vector table (VIM RAM).

   Once the VIM receives an interrupt, it loads the address of ISR from interrupt vector table, and store it into the interrupt vector register (IRQVECREG for IRQ interrupt, FIQVECREG for FIQ interrupt).

   After the interrupt is received by the CPU, the CPU executes the instruction placed at 0x18 or 0x1C (IRQ or FIQ vector) to load the address of ISR (interrupt vector) from the interrupt vector register. Example 19-3 illustrates the configuration for the exception vectors using this mode.

3. Hardware vectored interrupts (automatically dispatch to ISR, IRQ only)

   Before enabling interrupts, the application software must initiate the interrupt vector table (VIM RAM) pointing to the ISR for each interrupt channel.

   After the interrupt (IRQ) is received by the CPU, CPU reads the address of ISR directly from the interface with VIM (VIC port) instead of branching to 0x18. The CPU will branch directly to the ISR.

   The hardware vectored interrupt behavior must be explicitly enabled by setting the vector enable (VE) bit in the CP15 R1 register. This bit resets to 0, so that the default state after reset is backward compatible to earlier ARM CPU. Example 19-1 shows how to enable the hardware vectored interrupt.

   NOTE: This mode is NOT available for FIQ.

4. Software-Based Priority Decoding Scheme

   If the application uses a software-based interrupt priority decoding scheme instead of the hardware vector capabilities, then there is an additional step which was not required on earlier devices. This version of the VIM will hold an interrupt request generated by a peripheral. When the software clears the interrupt condition in the source module (for example, RTI, GIO, and so on), then it must also perform an additional clear of the interrupt request in the VIM. This can be done by reading the IRQVECREG register (Section 19.9.15) or FIQVECREG register (Section 19.9.16), or by writing a 1 to the INTREQ(i) bit (Section 19.9.10) in the VIM. This is not necessary if any of the three previous methods are used as the interrupt request bit in the VIM will be automatically cleared when the vector is read.

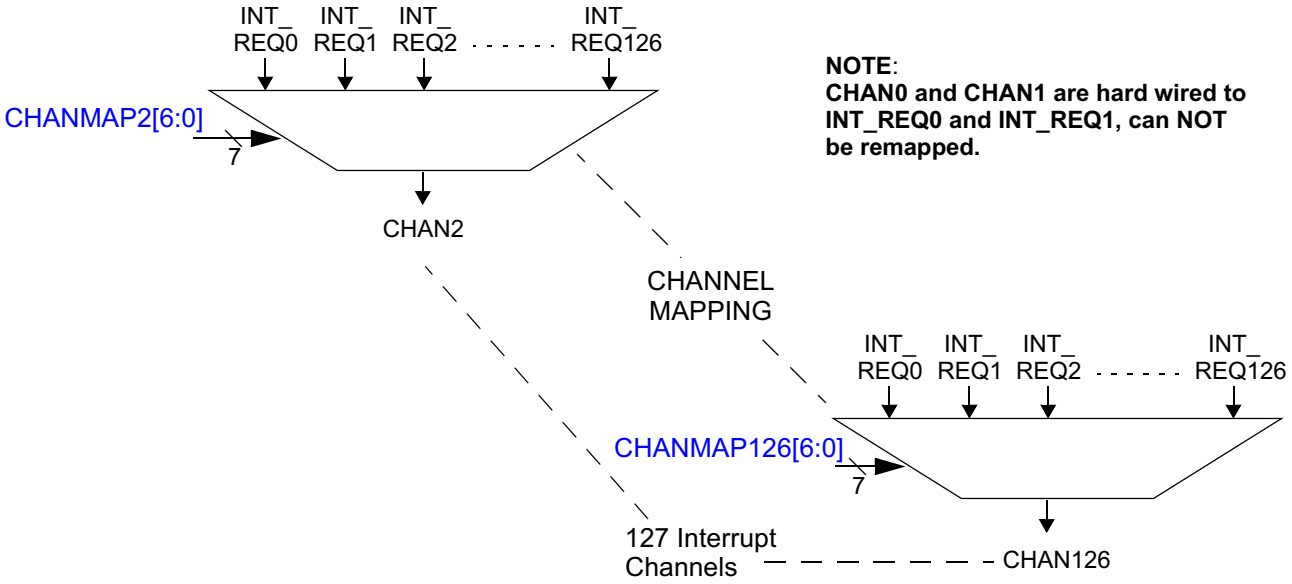
19.4 Interrupt Handling Inside VIM

A block diagram of the interrupt handling inside VIM is shown in Figure 19-3

Figure 19-3. VIM Interrupt Handling Block Diagram



Copyright © 2018, Texas Instruments Incorporated

19.4.1 VIM Interrupt Channel Mapping

The VIM support 128 interrupt channels (including phantom interrupt). A block diagram of the VIM interrupt requests arrangement from peripheral modules to the interrupt channels is provided in Figure 19-4. Each interrupt channel (CHANx) has a corresponding mapping register bit field (CHANMAPx[6:0]). This mapping register determines which interrupt channel it maps each VIM interrupt request. With this scheme, the same request can be mapped to multiple channels. A lower numbered channel in each FIQ and IRQ has higher priority. The programmability of the VIM allows software to control the interrupt priority.

Figure 19-4. VIM Channel Mapping

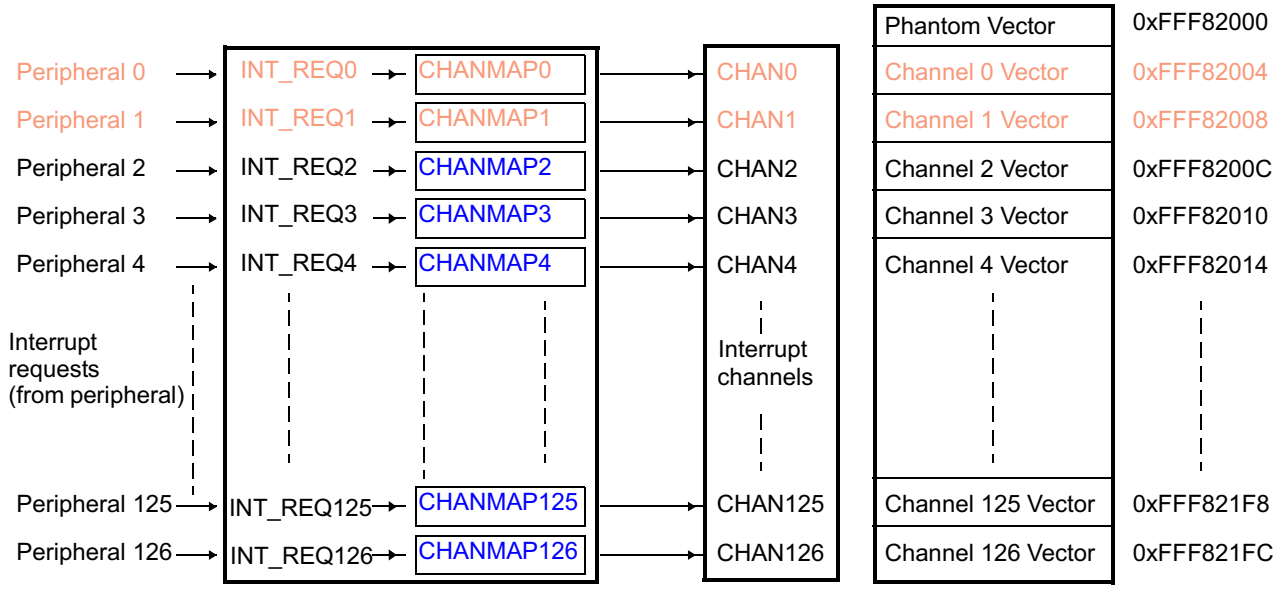
NOTE: CHAN127

CHAN127 has no dedicated interrupt vector table entry. Therefore, CHAN127 shall NOT be remapped to other INT_REQ (INT_REQ127 is reserved at device level).

In the reset state, the VIM maps all of the interrupt requests in the system to their respective interrupt channels. Figure 19-5 shows the default state following the reset.

Figure 19-6 shows the VIM INT2 is remapped to both Channel 2 and 4, and INT3 is mapped to channel 3.

NOTE: By mapping INT2 to channel 2 and channel 4, and mapping INT3 to channel 3, it is possible for the software to change the priority dynamically by changing the ENABLE register (REQENASET and REQENACLR). When channel 2 is enabled, the priority is:



1. INT0
2. INT1
3. INT2
4. INT3

Disabling channel 2, the priority becomes:

1. INT0
2. INT1
3. INT3
4. INT2

19.4.2 VIM Input Channel Management

As shown in Figure 19-7, the VIM enables channels on a channel-by-channel basis (in the REQENASET and REQENACLR registers); unused channels may be masked to prevent spurious interrupts.

NOTE: The interrupt ENABLE register does not affect the value of INTREQ.

Figure 19-7. Interrupt Channel Management

By default, interrupt CHAN0 is mapped to ESM (Error Signal Module) high level interrupt and CHAN1 is reserved for other NMI. For safety reasons, these two channels are mapped to FIQ only and can **NOT** be disabled through ENABLE registers.

NOTE: NMI Channel

Channel 0 and channel 1 are not maskable by the REQENASET / REQENACLR bit and both channel are routed exclusively to FIQ/NMI request line (FIRQPR0 and FIRQPR1 have no effect).

The VIM prioritizes the received interrupts based upon a programmed prioritization scheme. The VIM can send two interrupt requests to the CPU simultaneously—one IRQ and one FIQ. If both interrupt types are enabled at the CPU level, then the FIQ has greater priority and is handled first. Each interrupt channel, except channel 0 and 1, can be assigned to send either an FIQ or IRQ request to the CPU (in the FIRQPR register).

The VIM provides a default prioritization scheme, which sends the lowest numbered active channel (in each FIQ and IRQ classes) to the CPU. Within the FIQ and IRQ classes of interrupts, the lowest channel has the highest priority interrupt. The channel number is programmable through register CHANMAPx.

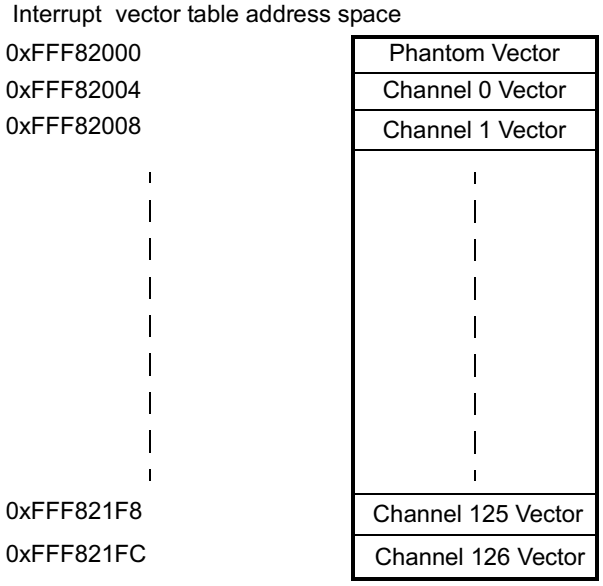
Copyright © 2018, Texas Instruments Incorporated

After the VIM has generated the vector corresponding to the highest active IRQ, it updates the FIQINDEX or the IRQINDEX register, depending on the class of interrupt. Then, it accesses the interrupt vector table using the vector value to fetch the address of the corresponding ISR. If the request is an FIQ class interrupt, the address read from the interrupt vector table, is written to the FIQVECREG register. If the request is an IRQ class interrupt, the address is written to the IRQVECREG register and put on the VIC port of the CPU (in case of hardware vectored interrupt is enabled).

All of the interrupt registers are updated when a new high priority interrupt line becomes active.

19.5 Interrupt Vector Table (VIM RAM)

Interrupt vector table stores the address of ISRs. During register vectored interrupt and hardware vectored interrupt, VIM accesses the interrupt vector table using the vector value to fetch the address of the corresponding ISR.



For safety reasons, the interrupt vector table has protection by ECC to indicate corruption due to soft errors. The ECC scheme is implemented as a continuous background check based on memory access. The ECC logic inside VIM supports Single-bit Error Correction and Double-bit Error Detection (SECDED). Section 19.5.1 through Section 19.5.4 describe how ECC works in the interrupt vector table.

NOTE: Writes to the interrupt vector table ECC status register (ECCSTAT) and the interrupt vector table ECC control register (ECCCTL) are in privilege mode only.

19.5.1 Interrupt Vector Table Operation

The interrupt vector table is organized in 128 words of 32 bits. Figure 19-8 shows the interrupt memory mapping. The table base address is 0xFFF82000.

Figure 19-8. VIM Interrupt Address Memory Map

NOTE: The interrupt vector table only has 128 entries, one phantom vector and 127 interrupt channels. Channel 127 does not have a dedicated vector and shall not be used.

Copyright © 2018, Texas Instruments Incorporated

There are seven bits of ECC per 32-bit ISR address. When a write is performed into the interrupt vector table, the ECC bits are calculated for the 32-bit word and written into the corresponding ECC region of interrupt vector table if ECC is enabled in VIM.

NOTE: Only 32-bit write/read access are allowed on interrupt vector table if ECC is required. Non 32-bit access might result in ECC errors.

When a read occurs from the CPU or VIM, the VIM calculates the ECC bits from the data coming from the interrupt vector table and compares it to the known good ECC value stored in the table. If a single-bit error is detected in the data, the SECDED block will automatically correct it. The read data will be a corrected one in this case. If double-bit errors are detected, the read data will be the uncorrected one. The access of the data and the ECC bits are performed in the same clock cycle.

The Double-Bit Error (DBE) and Single-Bit Error (SBE) events will be generated only if the ECC feature is enabled by ECCENA field. Correction of the data upon a SBE event will be done only if enabled EDAC_MODE field. Any double-bit error will be flagged out to ESM module and as UERR flag in ECCSTAT register. The address of the data for which UERR is detected will also be stored as UERRADDR register.

Any single-bit error will be registered into SBERR flag in ECCSTAT register and the corresponding address will be captured as SBERRADDR register. If SBE_INT_EN field on ECCCTL register is set to enable value, then it will be flagged out to ESM module.

Since the interrupt vector table may have an uncorrectable error (for example, DBE), the FBVECADDR register will provide to the VIC port, IRQVECREG and FIQVECREG, a fall-back address to an ISR that can restore the interrupt vector table content. The FB_VECADDR register should be set before initializing the interrupt in the interrupt vector table, to avoid branching to an unpredictable location.

The normal operation is restored when the ECCSTAT is cleared by the CPU. It is recommended to restore the content of the VIM before clearing the ECCSTAT.

19.5.2 VIM ECC Syndrome

The VIM ECC is controlled by the ECCENA bits of ECCCTL register. After reset, the SECDED feature is disabled. The SECDED feature can be enabled by writing 0xA (1010b) in the ECCENA[3:0] bit field of the ECCCTL register.

The ECC generation is done according to the ECC syndrome table as shown in Table 19-1 and Table 19-2. Each ECC bit is built by generating the parity of the XORed bits of the data word, whereas ECC bit 2 and 3 are even parity and the other bits odd parity.

Table 19-1. ECC Syndrome Table

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	ECC
x	x	x	x	x	x	x	x																	x	x	x	x	x	x	x	x	6

x							6
	x						5
		x					4
			x				3
				x			2
					x		1
						x	0

19.5.3 Interrupt Vector Table Initialization

After reset, the interrupt vector table content, including the ECC bits is not initialized. Therefore, the interrupt vector table has to be initialized first before enabling the corresponding interrupt channel. This can be done either using the hardware initialization mechanism (in Chapter Architecture Overview) or it can be done by writing known values into the interrupt vector table by software. If ECC is required, this initialization should be done after the ECC functionality is enabled. In this way, the corresponding ECC bits will be automatically updated. This initialization is only required when vectored interrupts are used, index interrupt management does not need the table to be initialized.

19.5.4 Interrupt Vector Table ECC Testing

To test the ECC checking mechanism, the ECC bits allows manual insertion of faults. This option is implemented using the TEST_DIAG_EN bit in the ECCCTL register control bit. Once TEST_DIAG_EN is enabled, the ECC bits are mapped to 0xFFF82400. In this mode, the user can modify the ECC bits without changing the data bits. If ECCENA is disabled, writing to data bits does not automatically update ECC bits. The CPU reads and writes under different conditions are summarized in Table 19-3 and Table 19-4. After that, user can force faults into either the data or the ECC bits. Finally, the ECC error can be triggered by reading interrupt vector table (not ECC bits) from VIM or CPU. Please note that no ECC checking will be done for reads of ECC bits in test mode.

Table 19-3. CPU Reads - Address Bit 10 Selects Between Normal Data and ECC Bits

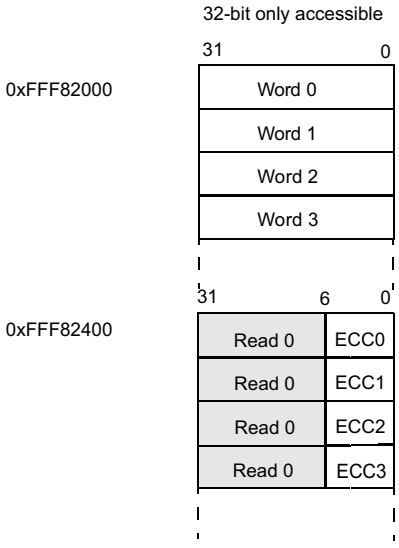
VBUSP_ ADDR(10)	TEST_DIAG_ EN	ECCENA	Action
0	x(don't care)	x(don't care)	Normal RAM location read
1	x	x	ECC bits read

Table 19-4. CPU Writes - Address Bit 10 Selects Between Normal Data and ECC Bits

VBUSP_ ADDR(10)	TEST_DIAG_ EN	ECCENA	Action
0	x	1	Normal RAM locations write with ECC bits
1	0	1	This write will be blocked
1	1	1	ECC bits write
0	x	0	Normal RAM locations write without ECC bits
1	0	0	This write will be blocked
1	1	0	This write is not allowed

Copyright © 2018, Texas Instruments Incorporated

The following sequence should be used for injecting faults to ECC bits and testing the ECC check feature.



1. Write the data locations of VIM RAM with the required patterns while keeping ECCENA active. The ECC bits will be automatically initialized along with data bits.
2. Enable ECC test mode using TEST_DIAG_EN field of ECCCTRL register.
3. In this mode, it is possible to corrupt ECC bits using any of the following methods.
   - Read the ECC bits, flip one bit and write back
   - Read the ECC bits, flip 2 bits and write back
4. Depending on the kind corruption created, read back the data bits and check for the correction error (single-bit error or double-bit error or no error).
5. Read the UERRADDR and SBERRADDR registers and check for the correct address capture as well.

The following sequence should be used for injecting faults to data bits and testing the ECC check feature.

1. Write the data locations of VIM RAM with the required patterns while keeping ECCENA active. The ECC bits will be automatically initialized along with data bits.
2. Disable ECC by setting ECCENA=0 in ECCCTRL register. In this mode, writing to data bits does not automatically update ECC bits.
3. In this mode, it is possible to corrupt data bits using any of the following methods.
   - Read the data bits, flip one bit and write back
   - Read the data bits, flip 2 bits and write back
4. Depending on the kind corruption created, read back the data bits and check for the correction error (single-bit error or double-bit error or no error).
5. Read the UERRADDR and SBERRADDR registers and check for the correct address capture as well.

NOTE: After completing the tests for ECC check features, it should be ensured that VIM Interrupt Vector Table is initialized with valid data and corresponding check bits. Care should also be taken to clear the UERR and SBERR flag registers and the error address registers.

Figure 19-9. ECC Bits Mapping

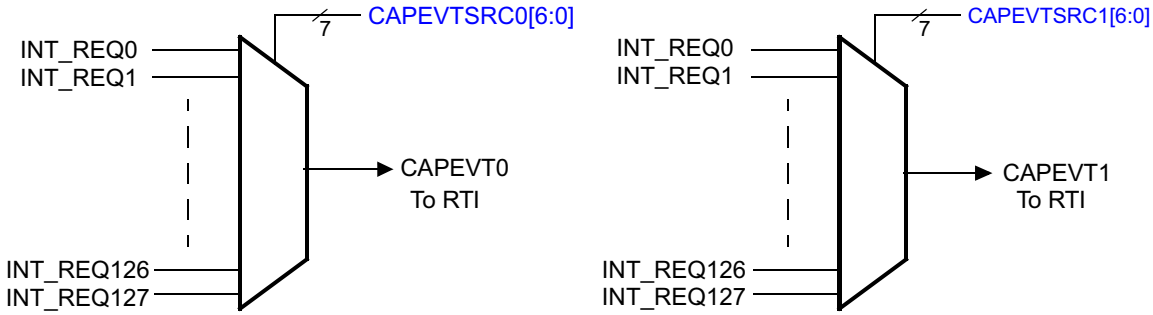
19.6 VIM Wakeup Interrupt

The wakeup interrupts are used to come out of low power mode (LPM). Any interrupt requests can be used to wake up the device. After reset, all interrupt requests are set to wake up from LPM. However, the VIM can mask unwanted interrupt lines for wake-up by using the WAKEENASET and WAKEENACLR register. The value in REQENASET / REQENACLR does NOT impact the wakeup interrupt.

As shown in Figure 19-10, the WAKEENASET and WAKEENACLR registers will enable/disable an interrupt for wake-up from low-power mode. All wake-up interrupts are “ORed” into a single signal WAKE_INT connected to the Global Clock Module.

Figure 19-10. Detail of the IRQ Input



Copyright © 2018, Texas Instruments Incorporated

19.7 Capture Event Sources

The VIM can select any of the 128 interrupt request to generate up to two capture events for the real-time interrupt (RTI) module (see Figure 19-11). The value in REQENASET / REQENACLR does NOT impact the capture event. Two registers (Section 19.9.17) are available, one for each capture event source.

Figure 19-11. Capture Event Sources

19.8 Examples

The following sections provide examples about the operation of the VIM.

19.8.1 Examples - Configure CPU To Receive Interrupts

Example 19-1 shows how to set the vector enable (VE) bit in the CP15 R1 register to enable the hardware vector interrupt. Example 19-2 shows how to enable/disable the IRQ and FIQ through CPSR. As a convention, the program who calls these subroutines shall preserve register R1 if needed. Example 19-2 can ONLY run in privileged mode. However, in USER mode, the application software can force the program into software interrupt by instruction 'SWI'. Then, in the software interrupt service routine, user can write register SPSR, which is the copy of CPSR in this exception mode.

Example 19-1. Enable Hardware Vector Interrupt (IRQ Only)

```
_HW_Vec_Init
    MRC p15 ,#0 ,R1 ,c1 ,c0 ,#0
    ORR R1 ,R1 ,#0x01000000       ; Mask 0-31 bits except bit 24 in Sys
                                  ; Ctrl Reg of CORTEX-R4
    MCR p15 ,#0 ,R1 ,c1 ,c0 ,#0   ; Enable bit 24
    MOV PC, LR
```

Copyright © 2018, Texas Instruments Incorporated

Example 19-2. Enable/Disable IRQ/FIQ through CPSR

```
FIQENABLE .equ 0x40
IRQENABLE .equ 0x80
......
_Enable_Fiq
    MRS R1, CPSR
    BIC R1, R1, #FIQENABLE
    MSR CPSR, R1
    MOV PC, LR
......
_Disable_Irq
    MRS R1, CPSR
    ORR R1, R1, #IRQENABLE
    MSR CPSR, R1
    MOV PC, LR
......
_Enable_Irq
    MRS R1, CPSR
    BIC R1, R1, #IRQENABLE
    MSR CPSR, R1
    MOV PC, LR
```

19.8.2 Examples - Register Vector Interrupt and Index Interrupt Handling

Example 19-3 illustrates the configuration for the exception vectors in Register Vector Interrupt handling. After the interrupt is received by the CPU, the CPU branches to 0x18 (IRQ) or 0x1C (FIQ). The instruction placed here should be *LDR PC, [PC,#-0x1B0]*. The pending ISR address is written into the corresponding vector register (IRQVECREG for IRQ, FIQVECREG for FIQ). The CPU reads the content of the register and branches to the ISR.

Example 19-3. Exception Vector Configuration for VIM Vector

```
          .sect ".intvecs"
00000000h b _RESET             ; RESET interrupt
00000004h b _UNDEF_INST_INT    ; UNDEFINED INSTRUCTION interrupt
00000008h b _SW_INT            ; SOFTWARE interrupt
0000000Ch b _ABORT_PREF_INT    ; ABORT (PREFETCH) interrupt
00000010h b _ABORT_DATA_INT    ; ABORT (DATA) interrupt
00000014h b #-8                ; Reserved
00000018h ldr pc,[pc,#-0x1B0]  ; IRQ interrupt
0000001Ch ldr pc,[pc,#-0x1B0]  ; FIQ interrupt
```

NOTE: Program Counter (PC) always pointers two instructions beyond the current executed instruction. In this case, PC equals to '*0x18 or 0x1C + 0x08*'. The *LDR* instruction load the memory at '*PC - 0x1B0*', which is '*0x18 or 0x1C + 0x08 - 0x1B0* = 0xFFFFFE70 or 0xFFFFFE74'. These are the address of IRQVECREG and FIQVECREG, which store the pending ISR address.

Copyright © 2018, Texas Instruments Incorporated

Example 19-4 shows a fast response to the FIQ interrupt in Index Interrupt and can be applied to a system that has more than one channel assigned as a FIQ. It is built in Index Interrupt compatible with TMS470R1x legacy code.

Example 19-4. How to Respond to FIQ With Short Latency

```
          .sect ".intvecs"          ; Interrupt and exception vector sector
00000000h b _RESET                  ; RESET interrupt
00000004h b _UNDEF_INST_INT         ; UNDEFINED INSTRUCTION interrupt
00000008h b _SW_INT                 ; SOFTWARE interrupt
0000000Ch b _ABORT_PREF_INT         ; ABORT (PREFETCH) interrupt
00000010h b _ABORT_DATA_INT         ; ABORT (DATA) interrupt
00000014h b #-8                     ; Reserved
00000018h b _IRQ_ENTRY_0            ; IRQ interrupt
                                    ;*********************************
                                    ; INTERRUPT PROCESSING AREA
                                    ;*********************************
0000001Ch ldrb R8, [PC,#-0x21d]     ; FIQ INTERRUPT ENTRY
                                    ; R8 used to get the FIQ index
                                    ; with address pointer to the
                                    ; first FIQ banked register
00000020h ldr PC, [PC, R8, LSL#2]   ; Branch to the indexed interrupt
                                    ; routine. The prefetch
                                    ; operation causes the PC to be 2
                                    ; words (8 bytes) ahead of the
                                    ; current instruction, so
                                    ; pointing to _INT_TABLE.
00000024h nop                       ; Required due to pipeline.
                                    ;=================================
00000028h _INT_TABLE                ; FIQ INTERRUPT DISPATCH
                                    ;=================================
0000002Ch .word _FIQ_TABLE          ; beginning of FIQ Dispatch
00000030h .word _ISR1               ; dispatch to interrupt routine 1
00000034h .word _ISR2               ; dispatch to interrupt routine 2
          .
          .
```

Another way to improve the FIQ latency is to assign only one channel to the FIQ interrupt and to map the ISR code corresponding to this channel directly starting at 0x1C.

NOTE: When the CPU is in vector-enabled mode, Example 19-3 and Example 19-4 are still valid. The difference is that the CPU will not read from the 0x18 location during IRQ interrupt, but will jump directly to the corresponding ISR routine.

19.9 VIM Control Registers

Table 19-5 lists the VIM module registers. Each register begins on a word boundary. All registers are 32-bit, 16-bit, and 8-bit accessible for read and write. Write is only possible in privilege mode. The base address of the control registers is FFFF FE00h. The base address of the ECC-related VIM registers is FFFF FD00h. The address locations not listed are reserved.

19.9.1 Interrupt Vector Table ECC Status Register (ECCSTAT)

Figure 19-12 and Table 19-6 describe this register.

Figure 19-12. Interrupt Vector Table ECC Status Register (ECCSTAT) [offset = ECh]

31	16
Reserved	
R-0	

15	9	8	7	1	0
Reserved		SBERR	Reserved		UERR
R-0		R/W1CP-0	R-0		R/W1CP-0

LEGEND: R/W = Read/Write; R = Read only; W1CP = Write 1 to clear in privilege mode only; -*n* = value after reset

Table 19-6. Interrupt Vector Table ECC Status Register (ECCSTAT) Field Descriptions

Bit	Field	Value	Description
31-9	Reserved	0	Reads return 0. Writes have no effect.
8	SBERR		The SBERR indicates that a single-bit error has been detected and has been corrected by the SECDED logic and the Interrupt Vector Table is being used for normal operation (not bypassed).
		0	*Read:* No single-bit error has occurred. *Write:* No effect.
		1	*Read:* A single-bit error has occurred and was corrected by the SECDED logic. *Write:* The SBERR bit is cleared.
7-1	Reserved	0	Reads return 0. Writes have no effect.
0	UERR		The UERR indicates that a double-bit error has been found and that the Interrupt Vector Table is bypassed. The resulting vector of any IRQ/FRQ interrupt is then the value contained in the FBVECADDR register until this bit has been cleared.
		0	*Read:* No double-bit error has occurred. *Write:* No effect.
		1	*Read:* A double-bit error has occurred and the Interrupt Vector Table is bypassed. *Write:* The UERR bit is cleared and the interrupt vector can be read from the Interrupt Vector Table.

19.9.2 Interrupt Vector Table ECC Control Register (ECCCTL)

Figure 19-13. Interrupt Vector Table ECC Control Register (ECCCTL) [offset = F0h]

31 28	27 24	23 20	19 16
Reserved	SBE_EVT_EN	Reserved	EDAC_MODE
R-0	R/WP-5h	R-0	R/WP-Ah

15 12	11 8	7 4	3 0
Reserved	TEST_DIAG_EN	Reserved	ECCENA
R-0	R/WP-Ah	R-0	R/WP-5h

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privilege mode only; -*n* = value after reset

Table 19-7. Interrupt Vector Table ECC Control Register (ECCCTL) Field Descriptions

Bit	Field	Value	Description
31-28	Reserved	0	Reads return 0. Writes have no effect.
27-24	SBE_EVT_EN		These bits control the generation of Error signal out based on Single-Bit Error (SBE) indications from SECDED logic for the Interrupt Vector Table.
		5h	Disable Error Event indication upon detection of SBE on the Interrupt Vector Table.
		Ah	Enable Error Event upon detection of SBE the Interrupt Vector Table.
		All other values	Writes are ignored and the values are not updated into this field. The state of the feature remains unchanged.
23-20	Reserved	0	Reads return 0. Writes have no effect.
19-16	EDAC_MODE		These bits determine whether Single-Bit Errors (SBE) detected by the SECDED block will be corrected or not.
		5h	Disable correction of SBE detected by the SECDED block.
		Ah	Enable correction of SBE detected by the SECDED block.
		All other values	Writes are ignored and the values are not updated into this field. The state of the feature remains unchanged.
			Note: If an SBE is selected to be not corrected (using EDAC_MODE), then an SBE event will also cause VIM RAM to be bypassed just like UERR and the module to use the FBVECADDR register as the vector address.
15-12	Reserved	0	Reads return 0. Writes have no effect.
11-8	TEST_DIAG_EN		This bit maps the ECC bits into the Interrupt Vector Table frame to make them accessible by the CPU. When enabled, the ECC bits are writable as well as readable independent of data bits.
		5h	Enable memory-mapping of ECC bits for read/write operation.
		All other values	Disable memory-mapping of ECC bits for read/write operation.
			Note: To avoid soft error to disable VIM ECC mapping, it is recommended to write Ah to disable ECC bits mapping.
7-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	ECCENA		VIM ECC enable.
		5h	VIM ECC is disabled.
		All other values	VIM ECC is enabled.
			Note: To avoid soft error to disable VIM ECC checking, it is recommended to write Ah to enable ECC checking.

Copyright © 2018, Texas Instruments Incorporated

19.9.3 Uncorrectable Error Address Register (UERRADDR)

The uncorrectable error address register gives the address of the first uncorrectable error location.

NOTE: No computation is needed when reading the complete register to retrieve the address in the Interrupt Vector Table.

This register will never be reset by a power-on reset nor any other reset source.

Figure 19-14. Uncorrectable Error Address Register (UERRADDR) [offset = F4h]

LEGEND: R = Read only; x = value is indeterminate; -*n* = value after reset

Table 19-8. Uncorrectable Error Address Register (UERRADDR) Field Descriptions

Bit	Field	Description
31-10	Interrupt Vector Table offset	Interrupt Vector Table offset. Reads are always FFF8 2xxxh; writes have no effect.
9-2	ADDERR	Uncorrectable error address register. This register gives the address of the first encountered double-bit error since the flag has been clear. Subsequent ECC errors will not update this register until the UERR flag has been cleared. **Note: This register is valid only when PARFLG is set (see Section 19.9.1).**
1-0	Word offset	Word offset. Reads are always 0; writes have no effect.

19.9.4 Fallback Vector Address Register (FBVECADDR)

This register provides a fall-back address to the VIM if a uncorrectable error has occurred in the Interrupt Vector Table. Figure 19-15 and Table 19-9 describe this register.

NOTE: This register will never be reset by a power-on reset nor any other reset source.

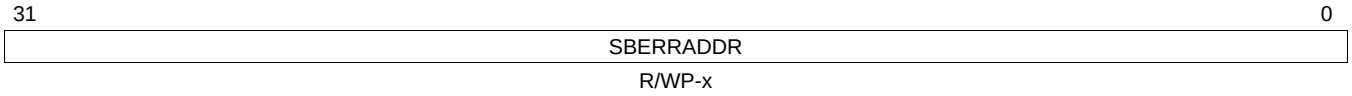
Figure 19-15. Fallback Vector Address Register (FBVECADDR) [offset = F8h]

31	0
FBVECADDR	
R/WP-x	

LEGEND: R/W = Read/Write; WP = Write in privilege mode only; x = value is indeterminate; -*n* = value after reset

Table 19-9. Fallback Vector Address Register (FBVECADDR) Field Descriptions

Bit	Field	Description
31-0	FBVECADDR	Fallback Vector Address Register. This register is used by the VIM if the Interrupt Vector Table has been corrupted. The contents of the IRQVECREG and FIQVECREG registers will reflect the value programmed in FBVECADDR. The value provided to the VIC port will also reflect FBVECADDR until the UERR register has been cleared. This register provides the address of the ISR that will restore the integrity of the Interrupt Vector Table.



Copyright © 2018, Texas Instruments Incorporated

19.9.5 Single-Bit Error Address Register (SBERRADDR)

This register gives the address of the first single-bit ECC error detected by the ECC logic.Figure 19-16 and Table 19-10 describe this register.

NOTE: This register will never be reset by a power-on reset nor any other reset source.

Figure 19-16. Single-Bit Error Address Register (SBERRADDR) [offset = FCh]

LEGEND: R/W = Read/Write; WP = Write in privilege mode only; x = value is indeterminate; -*n* = value after reset

Table 19-10. Single-Bit Error Address Register (SBERRADDR) Field Descriptions

Bit	Field	Description
31-0	SBERRADDR	Single-Bit Error Address Register. This register gives the address of the first single-bit error detected by the SECDED logic since the SBERR flag has been clear. Subsequent single-bit ECC errors will not update this register until the SBERR flag has been cleared. This register provides the Interrupt Vector Table address (offset from base address word aligned) of the ECC error location. This register is valid only when the SBERR flag is set.

19.9.6 VIM Offset Vector Registers

The VIM offset register provides the user with the numerical index value that represents the pending interrupt with the highest precedence. The register IRQINDEX holds the index to the highest priority IRQ interrupt; the register FIQINDEX holds the index to the highest priority FIQ interrupt. The index can be used to locate the interrupt routine in a dispatch table, as shown in Table 19-11.

Table 19-11. Interrupt Dispatch

IRQINDEX / FIQINDEX Register Bit Field	Highest Priority Pending Interrupt Enabled
0x00	No interrupt
0x01	Channel 0
:	:
0x7F	Channel 126
0x80	Channel 127

NOTE: Channel 127 has no dedicated interrupt vector table entry. Therefore, Channel 127 shall NOT be used in application.

The VIM offset registers are read only. They are updated continuously by the VIM. When an interrupt is serviced, the offset vectors show the index for the next highest pending interrupt or 0x0 if no interrupt is pending.

19.9.7 IRQ Index Offset Vector Register (IRQINDEX)

The IRQ offset register provides the user with the numerical index value that represents the pending IRQ interrupt with the highest priority. Figure 19-17 and Table 19-12 describe this register.

Figure 19-17. IRQ Index Offset Vector Register (IRQINDEX) [offset = 00h]

Table 19-12. IRQ Index Offset Vector Register (IRQINDEX) Field Descriptions

Bit	Field	Value	Description
31-8	Reserved	0	Reads return 0. Writes have no effect.
7-0	IRQINDEX	0-FFh	IRQ index vector. The least-significant bits represent the index of the IRQ pending interrupt with the highest precedence, as shown in Table 19-11. When no interrupts are pending, the least-significant byte of IRQINDEX is 0.

19.9.8 FIQ Index Offset Vector Registers (FIQINDEX)

The FIQINDEX register provides the user with a numerical index value that represents the pending FIQ interrupt with the highest priority. Figure 19-18 and Table 19-13 describe this register.

19.9.9 FIQ/IRQ Program Control Registers (FIRQPR[0:3])

The FIQ/IRQ program control registers determine whether a given interrupt request will be either FIQ or IRQ. Figure 19-19, Figure 19-20, Figure 19-21, Figure 19-22 and Table 19-14 describe these registers.

NOTE: Channel 0 and 1 are FIQ only, not impacted by this register.

19.9.10 Pending Interrupt Read Location Registers (INTREQ[0:3])

The pending interrupt register gives the pending interrupt requests. The register is updated every vbus clock cycle. Figure 19-23, Figure 19-24, Figure 19-25, Figure 19-26 and Table 19-15 describe this register.

19.9.11 Interrupt Enable Set Registers (REQENASET[0:3])

The interrupt register enable selectively enables individual request channels. Figure 19-27, Figure 19-28, Figure 19-29, Figure 19-30 and Table 19-16 describe these registers.

NOTE: Channel 0 and 1 are always enabled, not impacted by this register.

19.9.18 VIM Interrupt Control Registers (CHANCTRL[0:31])

Thirty-two interrupt control registers control the 128 interrupt channels of the VIM. Each register controls four interrupt channels: each of them is indexed from 0 to 127. Table 19-23 shows the organization of all the registers and the reset value of each. Each four fields of the register has been named with a generic index that refers to the detailed register organization. Figure 19-46 and Table 19-24 describe these registers.

Table 19-23. Interrupt Control Registers Organization

Address	Register Acronym	Register Field 31:24 $CHANMAPx_0$	Register Field 23:16 $CHANMAPx_1$	Register Field 15:8 $CHANMAPx_2$	Register Field 7:0 $CHANMAPx_3$	Reset Value
FFFF FE80h	CHANCTRL0	CHANMAP0	CHANMAP1	CHANMAP2	CHANMAP3	0001 0203h
FFFF FE84h	CHANCTRL1	CHANMAP4	CHANMAP5	CHANMAP6	CHANMAP7	0405 0607h
:	:	:	:	:	:	:
FFFF FEF8h	CHANCTRL30	CHANMAP120	CHANMAP121	CHANMAP122	CHANMAP123	7879 7A7Bh
FFFF FEFCh	CHANCTRL31	CHANMAP124	CHANMAP125	CHANMAP126	CHANMAP127	7C7D 7E7Fh

NOTE: CHANMAP0 and CHANMAP1 are not programable. CHAN0 and CHAN1 are hard wired to INT_REQ0 and INT_REQ1.

Do NOT write any value other than 0x7F to CHANMAP127. Channel 127 is reserved because no interrupt vector table entry supports this channel.

Direct Memory Access Controller (DMA) Module

This chapter describes the direct memory access (DMA) controller.

Topic **Page**

20.1 Overview **697**
20.2 Module Operation **699**
20.3 Control Registers and Control Packets **721**

Copyright © 2018, Texas Instruments Incorporated

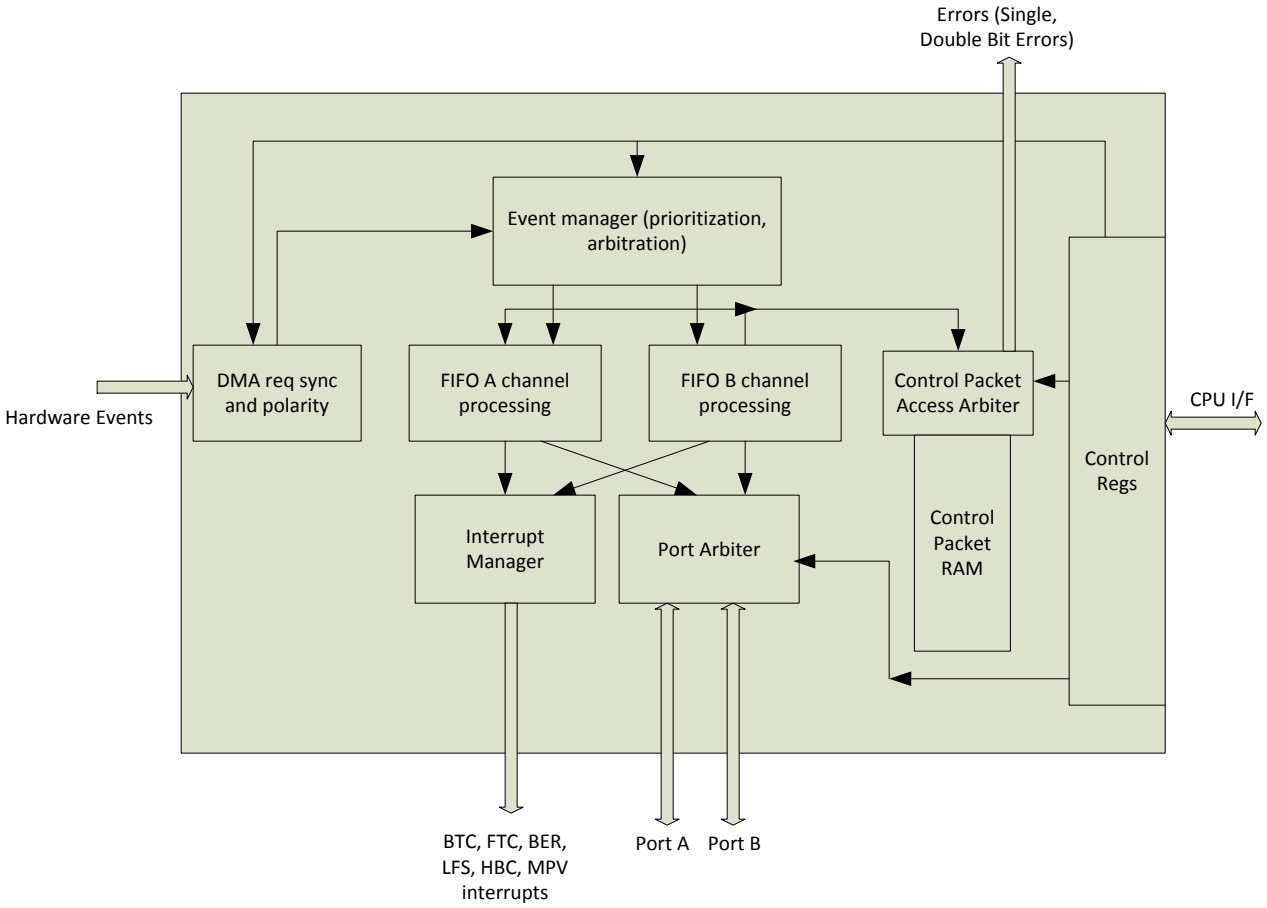
20.1 Overview

The DMA controller is used to transfer data between two locations in the memory map in the background of CPU operations. Typically, the DMA is used to:

- Transfer blocks of data between external and internal data memories
- Restructure portions of internal data memory
- Continually service a peripheral
- Page program sections to internal program memory

Since the DMA has two master ports, the selection for the port should be made using the table mentioning the port to be used for each address region.

20.1.1 Main Features



- CPU independent data transfer
- Two master ports - PortA and PortB (each 64-bits wide) that interface with the Microcontroller's Bus Matrix System.
- Support for concurrent transfers on up to two different channels
- FIFO buffer (4 entries deep and each 64-bits wide)
- Channel control information is stored in RAM protected by ECC
- Multiple logical channels with individual enable (refer to the data manual for the number of channels on your device)
- Channel chaining capability
- 48 peripheral DMA requests
- Hardware and Software DMA requests
- 8-, 16-, 32-, or 64-bit transactions supported
- Multiple addressing modes for source/destination (fixed, increment, offset)
- Auto-initiation
- Power-management mode
- Memory Protection for the address range DMA can access with multiple configurable memory regions (refer datasheet for number of memory regions on your device)

20.1.1.1 Block Diagram

Figure 20-1 gives a top view of the DMA internal architecture. DMA data read and write access happen through either Port A or B. Both FIFO buffers are each 4 levels deep and 64-bits wide thus allowing a maximum of 32 bytes to be buffered inside the DMA per channel. DMA requests go into the DMA that can trigger DMA transfers. Five interrupt request lines go out of the DMA to signal that a certain transfer status is reached. Register banks hold the memory mapped DMA configuration registers. Local RAM consists of DMA control packets and is secured by ECC. All the programming / configuration of the DMA controller is done via the Peripheral bus.

Figure 20-1. DMA Block Diagram

Copyright © 2018, Texas Instruments Incorporated

20.1.2 System Resources Mapping

Table 20-1 shows how the system resources are mapped to either of the two DMA ports. In order to properly transfer data from one resource to another, the application must setup the PARx register according to Table 20-1.

Table 20-1. DMA Ports to System Resources Mapping

DMA Ports	System Resources
Port A	• L2 Flash • L2 SRAM • EMIF
Port B	• All peripherals, that is, MibSPI registers, DCAN registers • All peripheral memories, that is, MibSPI RAM, DCAN RAM

- Example 1: To transfer data from L2 Flash, L2 SRAM, or EMIF to any peripheral registers or peripheral memories, write 0x1 (Port A read, Port B write) to the respective channels in the PARx registers
- Example 2: To transfer data from any peripheral registers or peripheral memories to L2 SRAM or EMIF, write 0x0 (Port B read, Port A write) to the respective channels in the PARx registers
- Example 3: To transfer data from L2 Flash to L2 SRAM, write 0x2 (Port A) to the respective channels in the PARx registers
- Example 4: To transfer data from peripherals to another peripherals, write 0x3 (Port B) to the respective channels in the PARx registers.

20.2 Module Operation

The DMA acts as an independent master in the platform architecture. DMA will attempt to execute up to two channels at the same time to maximize system throughput. Each channel can be configured to utilize either Port A or B or both for the read and write accesses while storing the data in one of the FIFOs. Choice of Port A or Port B for a certain channel depends on the addresses chosen for the transfer and should be made by referring to Table 20-1. All DMA memory and register accesses are performed in user mode. If the DMA writes to registers which are only accessible in privileged mode, the write will not be performed.

The DMA registers and its local RAM can only be accessed in privilege mode. Therefore, it is not possible for the DMA to reprogram itself.

In order to further explain DMA operation, some terms are described below:

- Arbitration - A channel may get temporarily suspended in order to service a higher priority channel or when the channel is disabled on the fly. The channel is said to have been "arbitrated"
- Arbitration Boundary - Each time a channel finishes a chunk of transfer which can be a maximum of 32 bytes, it is said to have reached an arbitration boundary. The FIFO is empty at an arbitration boundary. The DMA will utilize this boundary to re-prioritize channels. Within an arbitration boundary, transfers can never be interrupted.

Copyright © 2018, Texas Instruments Incorporated

20.2.1 Memory Space

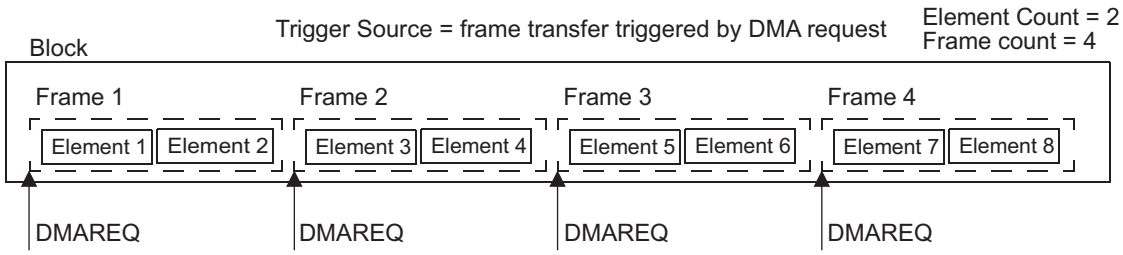
The DMA controller makes no distinction between program memory and data memory. The DMA controller can transfer to and from any space within the 4 gigabyte physical address map, by programming the absolute address for the source and destination in the control packet. Control packets store the transfer information such as source address, destination address, transfer count and control attributes for each channel.

20.2.2 DMA Data Access

The DMA controller refers to data in three levels of granularity:

- **Element:** Depending on the programmed data type, an 8-bit, 16-bit, 32-bit, or a 64-bit value. The type can be individually selected for the source (read) and destination (write). See Figure 20-2 and Figure 20-3 for an example of the use of elements. An element transfer cannot be interrupted.
- **Frame:** One or more elements to be transferred as a unit. A frame transfer can be interrupted between element transfers. See Figure 20-2 for an example. Use a frame size of one and frame transfer trigger source for transfers of one element per request.
- **Block:** One or more frames to be transferred as a unit. Each channel can transfer one block of data (once or multiple times). See Figure 20-3 for an example.

Figure 20-2. Example of a DMA Transfer Using Frame Trigger Source



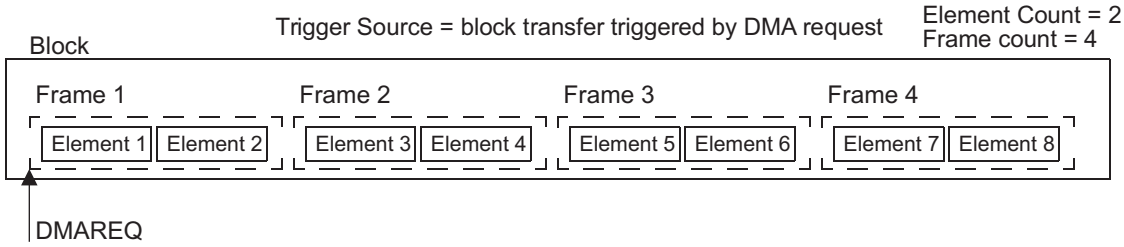


Figure 20-3. Example of a DMA Transfer Using Block Trigger Source

Copyright © 2018, Texas Instruments Incorporated

20.2.3 Addressing Modes

There are three addressing modes supported by the DMA controller that can be setup independent for the source and the destination address:

- Constant -- source and/or destination addresses do not change.
- Post incremented -- source and/or destination address are post-incremented by the element size.
- Indexed -- source and/or destination address is post-incremented as defined in the Element Index Offset Register (Section 20.3.2.5) and the Frame Index Offset Register (Section 20.3.2.6).

An unaligned address with respect to the element size is not supported.

20.2.4 DMA Channel Control Packets

Corresponding to each logical channel is a control packet that is mapped in fixed numerical order. For example, control packet 0 stores channel information for channel 0. The DMA requests can be mapped to the individual channels as described in Section 20.2.7. The mapping scheme between DMA requests and channels is shown in Figure 20-4. Each control packet contains nine fields. The first six fields compose the primary control packet and are programmable during DMA setup. The last three fields compose working control packet and are only readable by the CPU. The working control packets are used to support auto-initiation and prioritization of channels.. The organization of control packets is shown in Figure 20-5.

The primary control packet contains channel information such as source address, destination address, transfer count, element/frame offset value and channel configuration. Source address, destination address and transfer count also have their respective working images. The three fields of working images compose a working control packet and are not accessible to the CPU in write access.

The first time a DMA channel is selected for a transaction, the following process occurs:

1. The primary control packet is first read by the DMA state machine.
2. Once the channel is arbitrated, the current source address, destination address and transfer count are then copied to their respective working images.
3. When the channel is serviced again by the DMA, the state machine will read both the primary control packet and the working control packet to continue the DMA transaction until the end of an entire block transfer.

When the same channel is requested again, the state machine will start again by reading only the primary control packet and then continue the same process described above. The user software need not set up control packets again because the contents of the primary control packet were never lost. The working images of the control packets are reducing the software overhead and interaction with the DMA module to a minimum.

NOTE: Changing the contents of a channel control packet will clear the corresponding pending bit (Section 20.3.1.2) if the channel has a pending status. If the control packet of an active channel (as indicated in Section 20.3.1.3) is changed, then the channel will stop immediately at an arbitration boundary. When the same channel is triggered again, it will begin with the new control packet information.

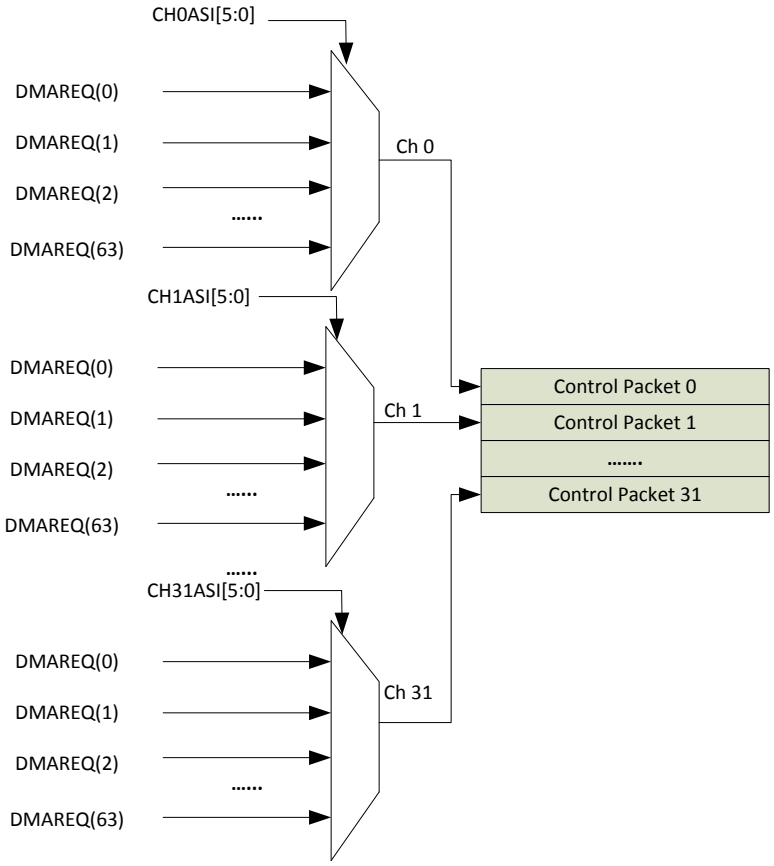
Figure 20-4. DMA Request Mapping and Control Packet Organization



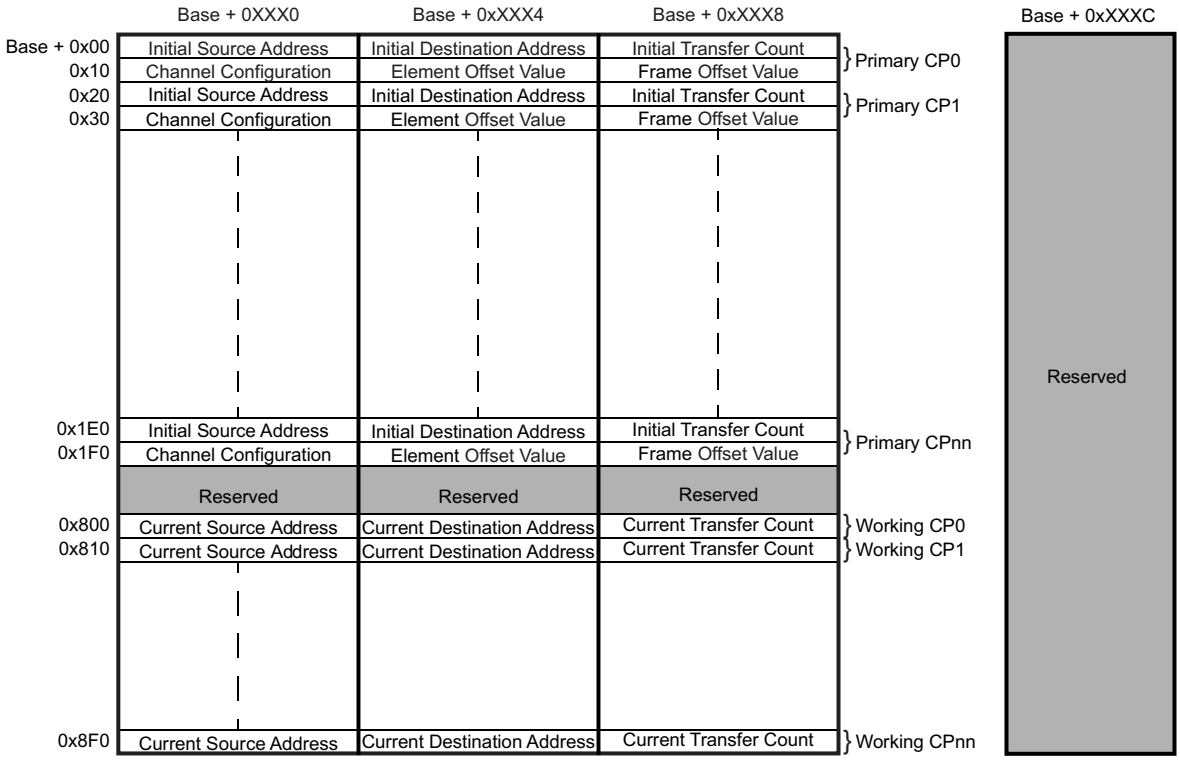


Figure 20-5. Control Packet Organization and Memory Map

Copyright © 2018, Texas Instruments Incorporated

20.2.4.1 Initial Source Address

This field stores the absolute 32-bit source address of the DMA transfer.

20.2.4.2 Initial Destination Address

This field stores the absolute 32-bit destination address of the DMA transfer.

20.2.4.3 Initial Transfer Count

The transfer count field is composed of two parts. The frame transfer count value and the element transfer count value. Each count value is 13-bits wide. As a Single Block transfer maximum of 512 Mbytes of data can be transferred. Element count and frame count are programmed according to the source data structure.

The total transfer size is calculated as:

$$T_{sz} = E_{rsz} \bullet E_{tc} \bullet F_{tc} \quad (26)$$

where

T_{sz} = Total Transfer Size

E_{rsz} = Read Element Size

E_{tc} = Element Transfer Count

F_{tc} = Frame Transfer Count

NOTE: A zero element count with a non-zero frame count or a non-zero element count with a zero frame count are all considered as zero total transfer count. No DMA transaction is initiated with any of the counters set to 0.

20.2.4.4 Channel Configuration Word

The channel configuration defines the following individual parameters:

- Read element size
- Write element size
- Trigger type (frame or block)
- Addressing mode for source
- Addressing mode for destination
- Auto-initiation mode
- Next control packet to be triggered at control packet finish (Channel Chaining)

20.2.4.5 Element/Frame Offset Value

There are 4 offset values that allow the creation of different types of buffers in RAM and address registers in a structured manner: an element offset value for source and destination and a frame offset value for source and destination.

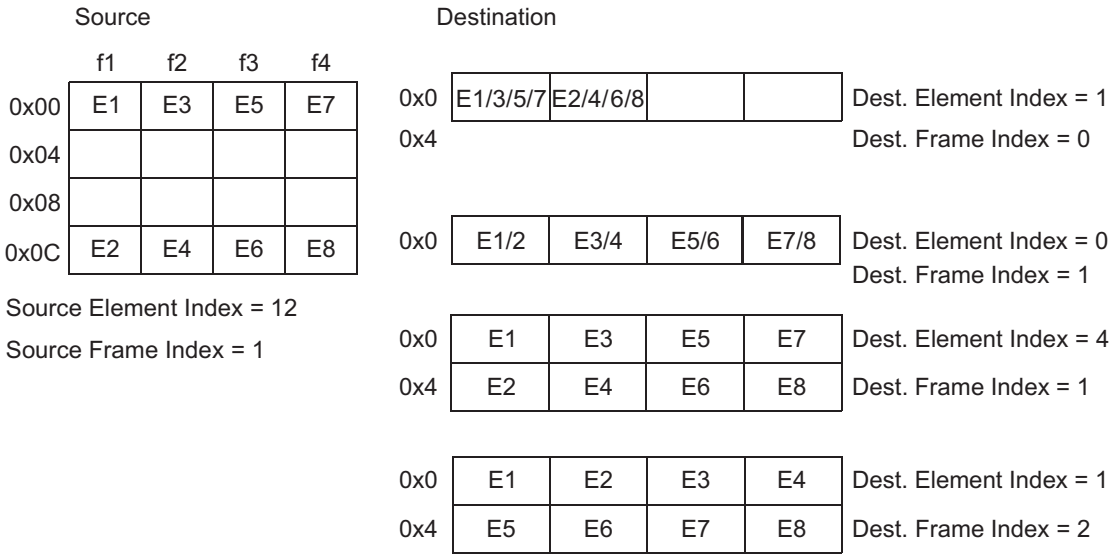
The element offset value for source and/or destination defines the offset to be added after each element transfer to the source and/or destination address. The frame offset value for source and/or destination defines the offset to be added to the source and/or destination address after the element count reaches zero. The element and frame offset values must be defined in terms of the number of bytes of offset. The DMA controller does not adjust the element/frame index number according to the element size. An index of 2 means *increment the address by 2* and not by 16 when the element size is 64 bits.

20.2.4.6 Current Source Address

The current source address field contains the current working source address during a DMA transaction. The current source address is incremented during post increment addressing mode or indexing mode.

Copyright © 2018, Texas Instruments Incorporated

20.2.4.7 Current Destination Address



The current destination address field contains the current working destination address during a DMA transaction. The current destination address is incremented during post-increment addressing mode or indexing mode.

20.2.4.8 Current Transfer Count

The current transfer count stores the remaining number of elements to be transferred in a block. It is decremented by one for each element read from the source location.

Figure 20-6, Figure 20-7, and Figure 20-8 show some examples of DMA transfers.

Figure 20-6. DMA Transfer Example 1

The example assumes the following setup.

Read Element Size = 8 bit
Write Element Size = 8 bit
Element Count = 2
Frame Count = 4

Figure 20-7. DMA Indexing Example 1

	f1		f2		f3		f4	
0x0	E1		E5		E9		E13	
0x10	E2		E6		E10		E14

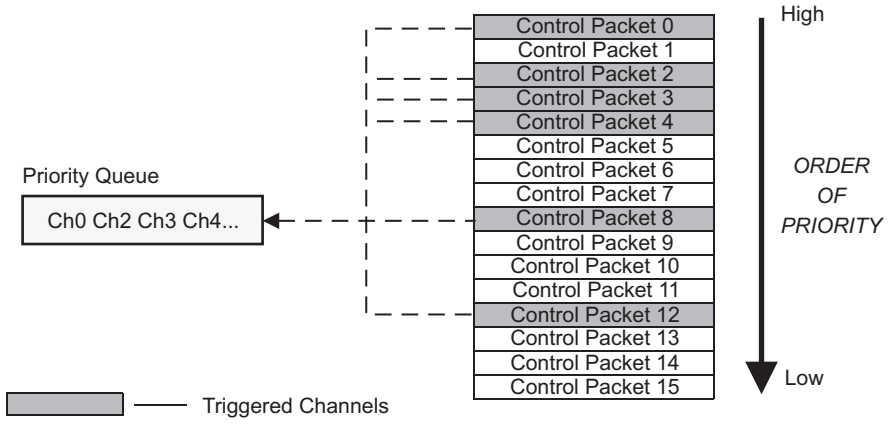
0x80	E3	E6	E9	E12	E15	E18	E21	E23

Element Index = 64
Frame Index = 4

This example can be applied to either source or destination indexing and assumes the following setup.



Element Size = 32 bit
Element Count = 3
Frame Count = 8

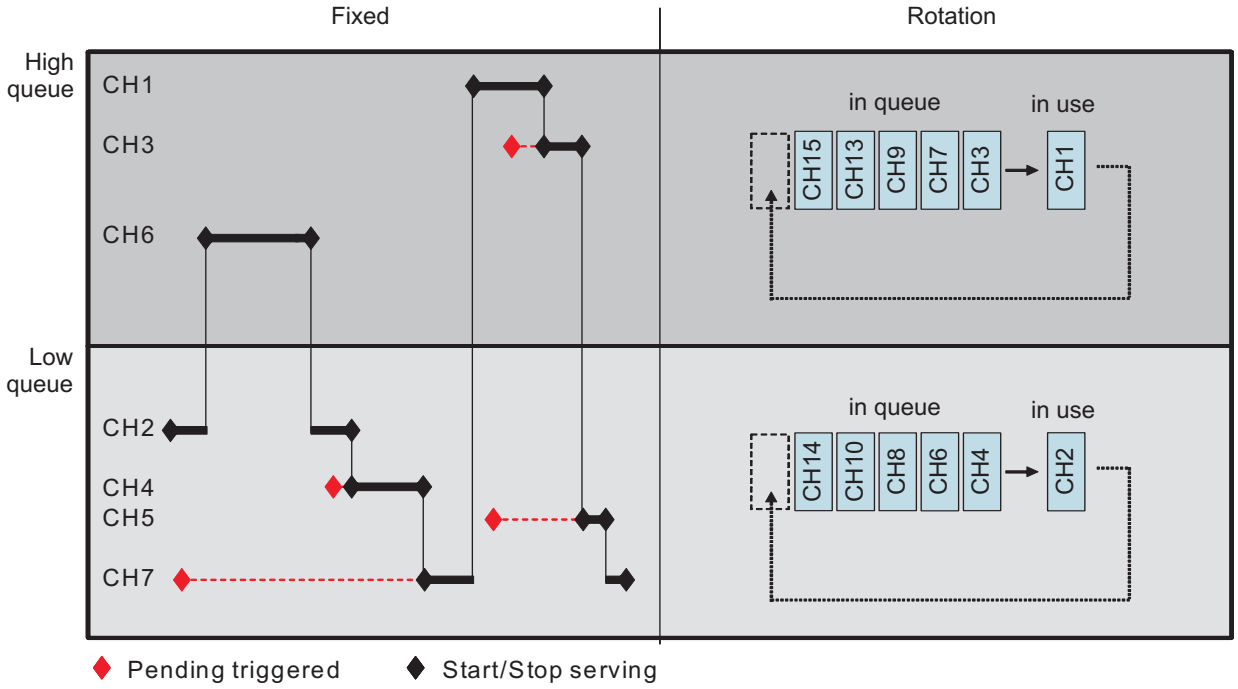
20.2.5 Priority Queue

User can assign channels in to priority queues to facilitate request handling during arbitration. The port has two priority queues: a high and a low priority queue. Each queue can be configured to follow a fixed or rotating priority scheme. Fixed priority is such that the lower the channel number (Figure 20-9), the higher its priority. Rotating priority is based on a round-robin scheme. Initially, the priority list is sorted according to the fixed priority scheme. Channels assigned to the high priority queue are always serviced first according to the selected priority scheme before channels in the low priority queue are serviced. Table 20-2 describes how arbitration is performed according to different priority schemes.

NOTE: Since the DMA controller provides the capability to map any one of the hardware DMA request lines to any channel, the numerical order of the hardware DMA request does not imply any priority. The priority of each hardware DMA request is programmed and determined by software.

Figure 20-9. Fixed Priority Scheme

The above figure illustrates that by default Lower the channel number, higher the Priority.



Copyright © 2018, Texas Instruments Incorporated

Table 20-2. Arbitration According to Priority Queues and Priority Schemes

Queue	Priority Scheme	Remark
High priority	Fixed	Channels are serviced in an ascending order according to the channel number. The lower the channel number, the higher the priority. A channel will be arbitrated out whenever there is a higher pending channel. Otherwise a channel is completely serviced until its transfer count reaches zero before the next highest pending channel is serviced. When there is no pending channels left in high queue then the DMA switches to service low queue channels.
	Rotating	Channels are arbitrated by using the round-robin scheme. Arbitration is performed when the FIFO is empty. When there are no pending channels left in high queue then the DMA switches to service low queue channels.
Low priority	Fixed	Channels are serviced in an ascending order according to the channel number. The lower the channel number the higher the priority. A channel will be arbitrated out whenever there is a higher-priority pending channel. Otherwise a channel is completely serviced until its transfer count reaches zero, before the next highest pending channel is serviced. If there is a pending channel in the high-priority queue while DMA is servicing a low queue channel then DMA will switch back to service high queue channel after an arbitration boundary.
	Rotating	Channels are arbitrated by using round-robin scheme. Arbitration is performed when the FIFO is empty.

A Simple Priority Queues example in both Fixed and Rotation Scheme is shown in Figure 20-10.

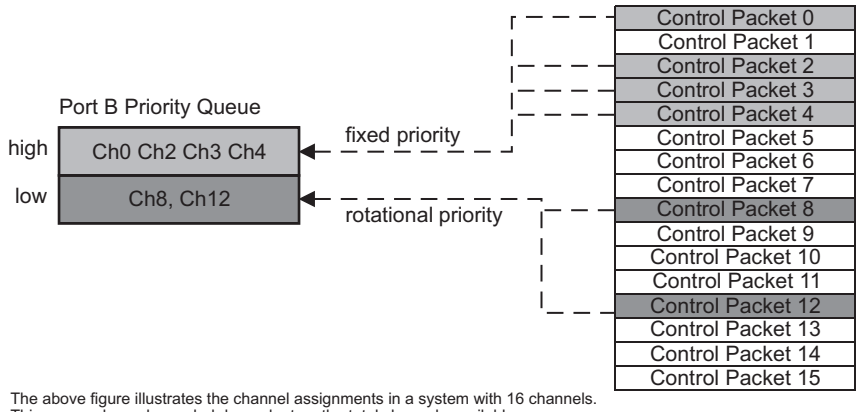


Figure 20-10. Example of Priority Queues

For optimal system performance, the high priority channels should be put in fixed arbitration scheme and low priority channels in the rotating priority scheme as illustrated in Figure 20-11.

Copyright © 2018, Texas Instruments Incorporated

Figure 20-11. Example Channel Assignments

1 The above figure illustrates the channel assignments in a system with 16 channels. This approach can be scaled dependent on the total channels available.

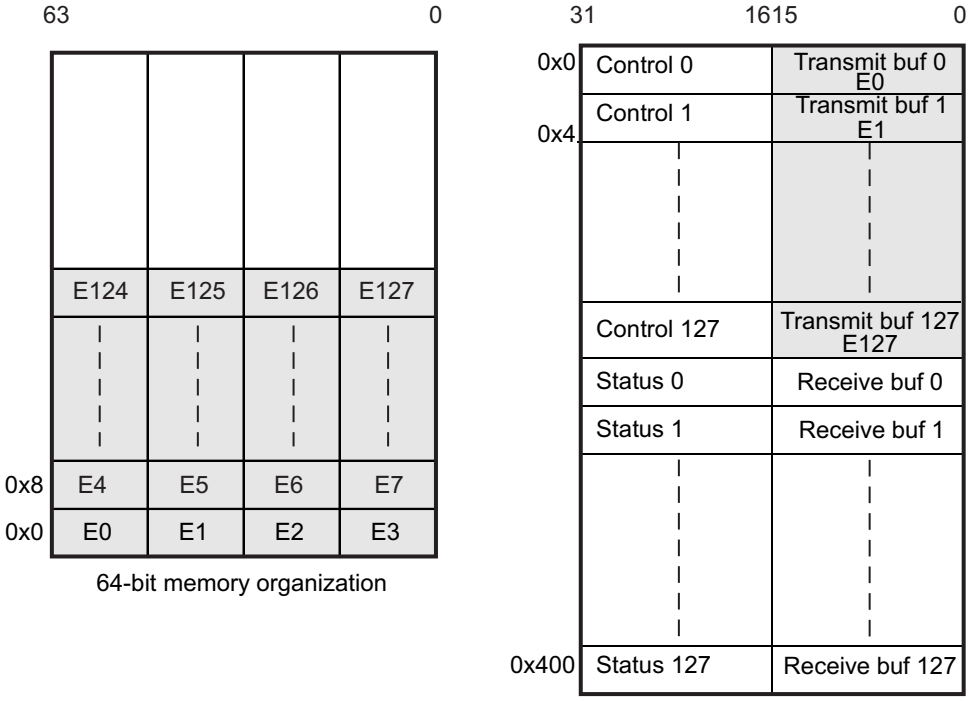
20.2.6 Data Packing and Unpacking

The DMA controller automatically performs the necessary data packing and unpacking when the read element size differs from the write element size. Data packing is required when the read element size is smaller than the write element size; data unpacking is required when the read element size is larger than the write element size. When the read element size is equal to the write element size, no packing is performed during read, nor is any unpacking performed during write.

Figure 20-12 shows an example of data unpacking in which the DMA is used to transfer 128 transmit data elements to the MibSPI FIFO buffer. In this example, data unpacking is required because the read element size is 64 while the write element size is 16. The DMA first performs an 64-bit read from the source into its FIFO buffer. After the 64-bit data is read into the DMA FIFO buffer, it must unpack the data into four 16-bit data elements before writing out to the destination. Therefore the DMA would need to perform four 16 bit write operations to the destination.

NOTE: Examples are shown for big-endian scheme.

NOTE: In the example in Figure 20-12, to transmit data at the lower bits of the MibSPI, bits 15:0, the destination address should be incremented by a factor of 2.



NOTE: 1) The element Count (Section 20.3.2.3) refers only to the read element.

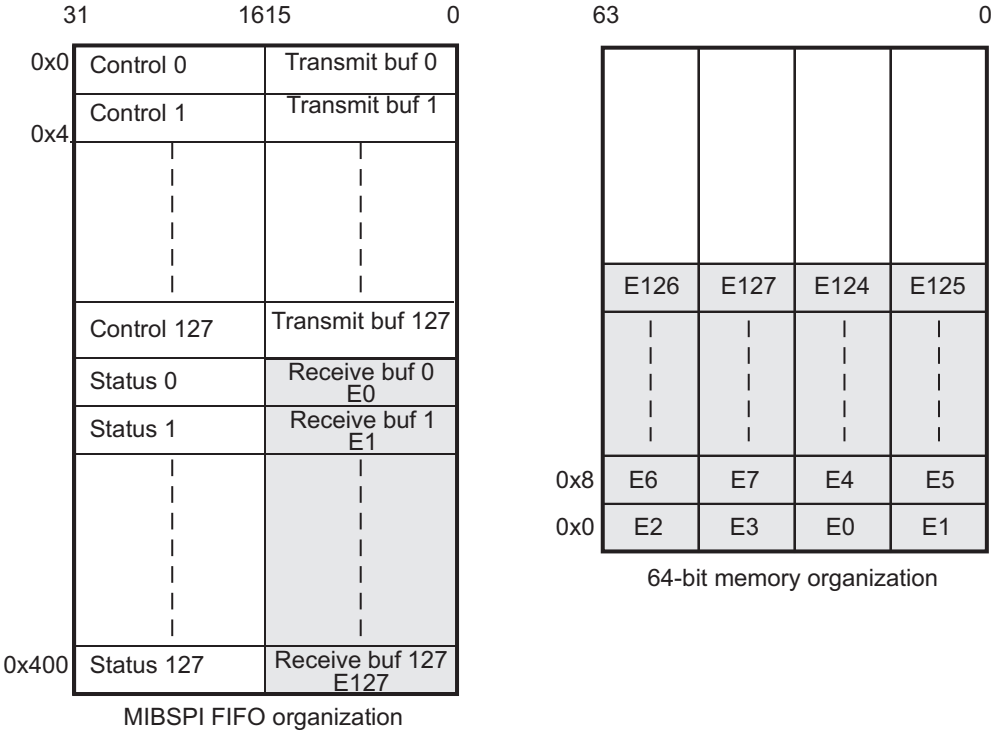
2) Data unpacking does not require the DMA request. Once the DMA request is received, data from Source is moved in to FIFO and unpacking happens until the FIFO is empty.

3) DMA assumes the destination is always ready and will perform write immediately. In case of data unpacking and Constant Addressing Mode write (Section 20.3.2.4 (1 - 0) = 0) the destination data will be overwritten by next data or next data might be skipped in case the destination has overflow protection (for example, SCITD register). User should configure DMA to avoid data unpacking if the Destination is configured as Constant Addressing Mode write to avoid data loss.

Copyright © 2018, Texas Instruments Incorporated

Figure 20-12. Example of DMA Data Unpacking

In this example, initialization of the MIBSPI FIFO is illustrated and assumes the following setup:



Read Element Size = 64 bit
Write Element Size = 16 bit
Element Count = 32
Frame Count = 1
Source Element Index = n/a, use post increment addressing mode
Source Frame Index = n/a, use post increment addressing mode
Destination Element Index = 4
Destination Frame Index = 0

When the read element size is smaller than the write element size, the DMA controller needs to perform data packing. The number of elements to pack is equal to the ratio between the write element size and read element size. In the example in Figure 20-13, the read element size is 16 bits and the write element size is 64 bits. The DMA controller would first pack the first four elements by performing four consecutive 16-bit read accesses of E0, E1, E2, and E3 into the first word of the DMA's internal FIFO. The DMA controller would then perform one single 64-bit write operation to transfer the data to the 64-bit destination memory.

Normally, the DMA controller carries out bus transactions on the bus according to the element size. For example, the DMA controller would perform a 16-bit read transaction if the read element size is programmed as 16 bits, or an 8-bit write transaction if the write element size is programmed as 8 bit. The exception is when the total transfer size is as defined in Equation 26 is not a multiple of the write element size.

Copyright © 2018, Texas Instruments Incorporated

Figure 20-13. Example of DMA Data Packing

In this example, a read of the MIBSPI FIFO is illustrated and assumes the following setup:

Read Element Size = 16 bit
Write Element Size = 64 bit
Element Count = 128
Frame Count = 1
Source Element Index = 4
Source Frame Index = 0
Destination Element Index = n/a, use post increment addressing mode
Destination Frame Index = n/a, use post increment addressing mode

For example, if the read element size is 8 bits, the element transfer count is equal to 9, and the write element size is 64 bit. The DMA controller would first perform eight 8-bit read transactions from the source. It would then perform a 64-bit write to the destination. When the same channel wins arbitration again, the DMA controller would first perform one 8-bit read from the source, followed by one 8-bit write to the destination, even though the write element size is 64 bit.

NOTE: Since peripherals are slower, it is advised to use data packing feature with caution for reading data from peripherals. Improper use might delay servicing other pending DMA channels.

Copyright © 2018, Texas Instruments Incorporated

20.2.7 DMA Request

There are three ways to start a DMA transfer:

- **Software request:** The transfer will be triggered by writing to SW Channel Enable Set and Status Register (Section 20.3.1.7). The software request can trigger either a block or a frame transfer depending on the setting of the TTYPE bit in the Channel Control Register (Section 20.3.2.4).
- **Hardware request**: The DMA controller can handle up to 48 DMA Request lines. A hardware request can trigger either a frame or a block transfer depending on the setting of the TTYPE bit in the Channel Control Register (Section 20.3.2.4).
- **Triggered by other control packet:** When a control packet finishes the programmed number of transfers it can trigger another channel to initiate its transfers.

Each time a DMA request is made, either one frame transfer or one block transfer can be chosen. An active DMA request signal will trigger a DMA transaction.

The DMA controller has a two-level buffer to capture HW requests per channel. When a HW request is generated and the channel is enabled, the corresponding bit in the DMA Status Register (Section 20.3.1.3) is set. The pending register acts as a first-level buffer. Typically, a peripheral acting as a source of a transfer could initiate another request after its data registers have been read out by DMA, even though that data has not been completely transferred to the destination. If a second HW request is generated by the peripheral, the DMA controller has an extra request buffer to capture this second request and service it after the first request is complete.

NOTE: The DMA cannot capture more than two requests at the same time. Additional requests are ignored until at least one pending request is completely processed.

The DMA controller also supports a mix of hardware and software requests on the same channel. Note that such interchangeable usage may result into an out of sync for DMA channel and peripheral. The application needs to be careful as the DMA does not have a built-in mechanism to protect against this loss of synchronization.

If a software request is generated, the corresponding bit in the Channel Pending Register (Section 20.3.1.2) is set accordingly. If the pending request is not completely serviced by the DMA and a hardware request is generated by a peripheral onto the same channel, the DMA will capture and recognize this hardware request into its request buffer.

NOTE: The DMA controller cannot recognize two software requests on the same channel if the first software request is still pending. If such a request occurs, the DMA will discard it. Therefore, the user software should check the pending register before issuing a new software request.

The DMA module on this microcontroller has 32 channels and up to 48 hardware DMA requests. The module contains DREQASIx registers which are used to map the DMA requests to the DMA channels. By default, channel 0 is mapped to request 0, channel 1 to request 1, and so on.

Some DMA requests have multiple sources, see Table 20-3. The application must ensure that only one of these DMA request sources is enabled at any time.

20.2.8 Auto-Initiation

When Auto-initiation Mode (AIM) bit of Channel Control Register (Section 20.3.2.4) is enabled for a channel and the channel is triggered by a software request for a block transfer, the channel will restart again using the same channel information stored at the respective control packet after one block transfer is completed. In the case of Hardware Request the channel needs to be retriggered each time after a block is complete even if auto-initiation is enabled.

20.2.9 Interrupts

Each channel can be configured to generate interrupts on several transfer conditions:

- Frame transfer complete (FTC) interrupt: an interrupt is issued after the last element of a frame has been transferred.
- Last frame transfer started (LFS) interrupt: an interrupt is issued before the first element of the last frame of a block transfer has started.
- First half of block complete (HBC) interrupt: an interrupt is issued if more than half of the block is transferred.
  - If the number of frames *n* is odd, then the HBC interrupt is generated at the end of the frame when *(n+1) / 2* number of frames are left in the block.
  - If the number of frames *n* is even, then the HBC interrupt is generated at the end of the frame after *n/2* number of frames are left in the block.
- Block transfer complete (BTC) interrupt: an interrupt is issued after the last element of the last frame has been transferred.
- External imprecise error on read: an interrupt can be issued when a bus error (Illegal transaction with ok response) is detected. The imprecise read error is connected to the ESM module.
- External imprecise error on write: an interrupt can be issued when a bus error (Illegal transaction with ok response) is detected. The imprecise write error is connected to the ESM module.
- Memory Protection Unit error (MPU): an interrupt is issued when the DMA detects that the access falls outside of a memory region programmed in the MPU registers of the DMA. The MPU interrupt is connected to the ESM module.
- Parity error (PAR): an interrupt is issued when the DMA detects a parity error when reading one of the control packets. The PAR interrupt is connected to the ESM module.

The DMA outputs 5 interrupt lines for control packet handling, a parity interrupt and a memory protection interrupt (Figure 20-14). Each type of transfer interrupt condition is grouped together. For example, all block-transfer complete interrupts that are routed to a port are combined (ORed). The channel that caused the interrupt is given in the corresponding interrupt channel offset register. Priority between interrupts among the same interrupt type is resolved by a fixed priority scheme. Priority between different interrupt types is resolved in the Vector Interrupt Manager. Figure 20-15 explains the Frame Transfer Complete Interrupt structure in detail.

NOTE: Each Channel Specific interrupts in DMA module are routed towards Group A or B to support two different CPUs individually. For devices with Single CPU or Dual CPU, where both CPUs are running same code in delayed lock-step as safety feature:

Group A - Interrupts (FTC, LFS, HBC, and BTC) are routed to the ARM CPU.

Group B - Interrupts (FTC, LFS, HBC, and BTC) are not routed out.

User software should configure only Group A interrupts.

20.2.10 Debugging

The DMA supports four different behaviors in suspend mode. These behaviors can be configured by the user as per the application requirement.

- Immediate stop at a DMA channel arbitration boundary. Please refer to Table 20-4 and Table 20-5 for arbitration boundary definition.
- Finish current frame transfer and continue after suspend ends.
- Finish current block transfer and continue after suspend ends.
- Ignore the suspend. The DMA continues to be operational as in functional mode when debug mode is active.

When the DMA controller enters suspend mode, it continues to sample incoming hardware DMA requests, but the Channel Pending Register (Section 20.3.1.2) is frozen from being updated. After the suspend ends, all new requests that were received during suspend mode are reflected in the Channel Pending Register (Section 20.3.1.2).

Except when the DMA controller is configured to ignore suspend mode, no channel arbitration is performed during suspend mode. The current channel under which suspend mode was entered will finish its entire frame or block-transfer after suspend mode ends, depending how the debug option was chosen.

To facilitate debugging, a Watch Point Register (Section 20.3.1.54) and a Watch Mask Register (Section 20.3.1.55) are used. The watch point register together with the watch mask register can be configured to watch for a unique address or a range of addresses. When the condition to watch is true, the DMA freezes its state and generates a debug request signal to the host CPU so the state of the DMA can be examined.

20.2.11 Power Management

The DMA offers two power-management modes: run and sleep. In run mode, the DMA is fully operational.

The sleep mode shuts down the DMA if no pending channels are waiting to be serviced. If a DMA request is received or a software request is generated by the user software, then the DMA wakes up immediately.

The sleep mode may be used to optimize the DMA module power consumption.

When the system module issues a global low power mode request, the DMA will respond to the system module with an acknowledge as soon as an arbitration boundary is reached. If no DMA requests are pending, it will respond with an acknowledge immediately.

NOTE: When the DMA is in global low power mode, the clock is stopped and therefore it cannot detect any DMA request. The device must be woken up before a peripheral can generate a DMA request.

Copyright © 2018, Texas Instruments Incorporated

20.2.12 FIFO Buffer

DMA FIFO is 4 levels deep and 64-bit wide (can hold up to 4 × 64-bits of data). They are used for Data packing and unpacking.

The DMA FIFO has two states:

- EMPTY: The FIFO contains no data.
- FULL: The FIFO is filled or the element count has reached zero; the read operation has to be stopped.

DMA channels can only be switched when the FIFO is empty. This also implies that arbitration between channels is done when the FIFO is empty.

The DMA has two FIFOs, FIFO A and FIFO B, each executing a channel that provides the capability to execute a maximum of two channels concurrently.

The FIFO buffer may be bypassed through the use of the bypass feature in the port control register; see Port Control Register (Section 20.3.1.51) for register details. Writing 1 to this bit limits the FIFO depth to the size of one element. That means if the read element size is equal to or larger than the write element size, after one element is read the write out to the destination starts. Otherwise, the write out to the destination starts after enough reads have completed to do one write of the write element size. This feature is particularly useful to minimize switching latency in-between channels. When bypass mode is enabled, the DMA performs minimal transfers within an arbitration boundary. In addition, the bypass feature allows arbitration between channels that can be carried out at a source element granularity.

However, it has to be considered that while in bypass mode, the DMA controller does not make optimal use of the bus bandwidth. Since the read and write element sizes can be different, then the number of read and write transactions will be different. Table 20-4 and Table 20-5 show a comparison between the number of read and write transactions performed by the DMA controller from one channel to another before arbitration in non-bypass and bypass mode.

Table 20-4. Maximum Number of DMA Transactions per Channel in Non-Bypass Mode

	Write Element Size	8 bit		16 bit		32 bit		64 bit	
Read Element Size	8 bit	4 read	4 write	4 read	2 write	4 read	1 write	8 read	1 write
	16 bit	2 read	4 write	4 read	4 write	4 read	2 write	4 read	1 write
	32 bit	1 read	4 write	2 read	4 write	4 read	4 write	4 read	2 write
	64 bit	1 read	8 write	1 read	4 write	2 read	4 write	4 read	4 write

Table 20-5. Maximum Number of DMA Transactions per Channel in Bypass Mode

	Write Element Size	8 bit		16 bit		32 bit		64 bit	
Read Element Size	8 bit	1 read	1 write	2 read	1 write	4 read	1 write	8 read	1 write
	16 bit	1 read	2 write	1 read	1 write	2 read	1 write	4 read	1 write
	32 bit	1 read	4 write	1 read	2 write	1 read	1 write	2 read	1 write
	64 bit	1 read	8 write	1 read	4 write	1 read	2 write	1 read	1 write

20.2.13 Channel Chaining

Channel chaining is used to trigger a single or multiple channels with out an external DMA request. This is possible by chaining one control packet to other. Chain[5:0] field of the Channel Control Register (Section 20.3.2.4) is used to program the chaining control packet. Chained control packets follow arbitration rules within the pending register. For example if CH1, CH2, CH4, CH5 are triggered together and CH3 is chained with CH1. The order of channels serviced in spite of chaining will be CH1 -> CH2 -> CH3 -> CH4 -> CH5.

In order to setup up channel chain feature, the Channel Control Register (Section 20.3.2.4) needs to be enabled for all chained channels before triggering first DMA request.

Figure 20-16 illustrates how internally chained request is generated after completing the required transfers and stored in pending register. In this example CH1 is Chained to CH0. When CH0 is triggered CH1 is captured as pending in the Channel Pending Register (Section 20.3.1.2) even when it is not triggered.

Figure 20-16. Example of Channel Chaining

20.2.14 Request Polarity

DMA supports both active high and active low hardware requests. This is configured through the registers DMAREQPS1 and DMAREQPS0.

The selection of request polarity should be done at the start of the program. In order to change the request polarity from active high to active low for a channel following sequence should be followed:

1. Disable channel for which polarity is to be changed using the HWCHENA bit.
2. Disable the peripheral in order that it may set the request line to inactive high state (since by default requests are active high).
3. Apply software reset to the DMA using the GCTRL register.
4. Program the request polarity for the channel.
5. Re-enable the DMA channel.
6. Re-enable the peripheral that triggers the DMA event.

Copyright © 2018, Texas Instruments Incorporated

20.2.15 Memory Protection

The DMA controller is capable of access to the full address range of the device. The protection mechanism allows the protection of multiple memory regions to restrict accesses to those address ranges. This will allow the application to protect critical application data from unintentionally being accessed by the DMA controller.

20.2.15.1 Protection Mechanism

The memory protection mechanism consists of the access privilege for a given memory region, the start and end address for the region, and notification of an access violation for the protected region.

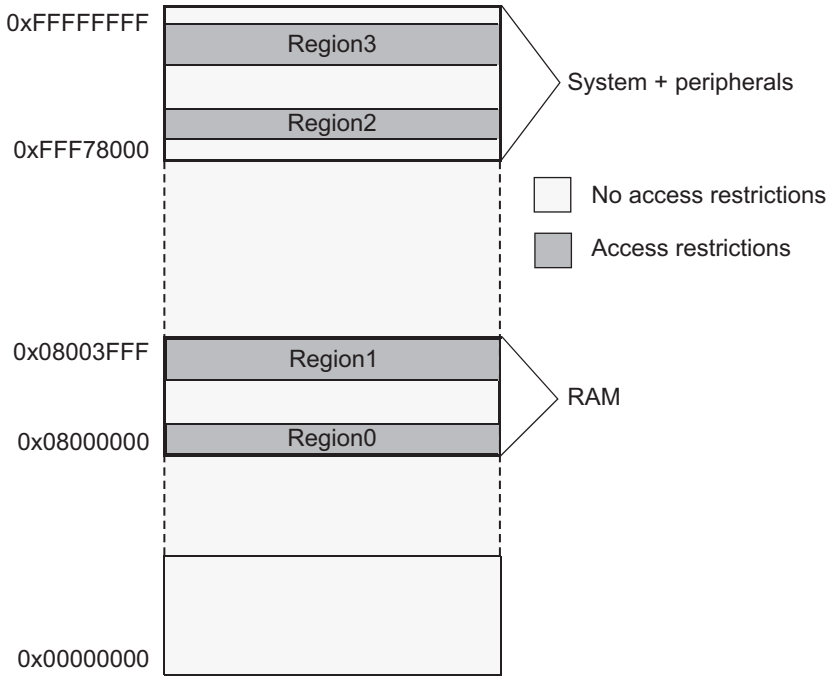
Each region to be protected is configured by software by writing the start address and end address for each region into the DMA Memory Protection Registers, DMAMPRxS and DMAMPRxE. The definition of these registers can be found starting at Section 20.3.1.64. Any region in the valid address space can be protected from inappropriate accesses.

The access privileges can be set to one of four permission settings as shown below:

- Full access
- Read only access
- Write only access
- No access

The permissions for a given region are selected by writing the appropriate values in the DMA Memory Protection Control Register (Section 20.3.1.64).

A region of memory not configured for access settings by the registers has "Full Access" privileges.



NOTE: If the regions defined by the start and end addresses overlap, the region defined first in the register space determines the access privilege. For example, if region 0 and region 1 overlap, the access permissions defined for region 0 will take precedence since region 0 registers are before region 1.

In a case where a memory protection violation occurs, a flag will be set and an interrupt will be generated, if interrupts are enabled. The DMA Memory Protection Status Register (Section 20.3.1.65) contains the status flags for the memory protection mechanism, and the DMA Memory Protection Control Register (Section 20.3.1.64) contains the interrupt enable bits. Upon detection of the memory protection violation, the DMA Channel that caused the violation will be stopped and the next available DMA channel will be serviced.

Figure 20-17 Illustrates a protection mechanism.

Figure 20-17. Example of Protection Mechanism

20.2.16 ECC Checking

The Control packet RAM is protected using a Single Error Correction Double Error Detection (SECDED) scheme. This scheme is implemented using a total of 9 ECC check bits for every 128 bits of data stored in the DMA Control Packet RAM.

ECC checking can be enabled and disabled within the module by a 4-bit key. The key is located in the ECC Control Register (Section 20.3.1.62).

During write accesses to Control Packet RAM, ECC bits are generated automatically and stored along with the data bits to the memory.

During read accesses from the Control Packet RAM, the ECC bits in memory are checked against a computed ECC value for the 128 bits of data. Following two kinds of errors can occur during the read:

- Single-Bit Error - If a single-bit error occurs during the reads to the control packet either by the CPU or by DMA logic and the EDCAMODE[3:0] in DMASECCCTRL register is 0xA, the error is automatically corrected. The SBEFLG bit in the register is also set to 1 to indicate a single-bit error was corrected. The DMAECCSBE register is updated to indicate the error address. In addition, if the SBE_EVT_EN[3:0] in DMASECCCTRL register is 0xA, the error is also indicated to ESM.
- Double-Bit Error - If a double-bit error occurs during the reads to the control packet either by the CPU or the DMA logic and the ECC_ENA[3:0] in DMAPECR register is 0xA, the error is indicated to ESM. The EDFLG bit gets set and the error address is stored in DMAPAR register.

The DMA module automatically performs read-modify-write operations to the Control Packet RAM which are required during CPU configuration of the control packet RAM. Errors occuring during these reads are also covered by the SECDED scheme. Also, reads to the Working Packet by CPU or DMA logic and writes to the Working Packet by the DMA logic are also protected by SECDED.

During double-bit errors, it is possible to configure the behavior of the channel using the ERRA bit in DMAPECR register. Two options are available:

- If ERRA bit is cleared, errors are ignored and channel operation will resume normally.
- If ERRA bit is set, errors will cause the DMA to be disabled (DMA_EN bit in GCTRL register is cleared). All channels will stop servicing at the next arbitration boundary. This action will be taken regardless of the origin of error being a CPU read or a DMA logic read.

Copyright © 2018, Texas Instruments Incorporated

20.2.17 ECC Testing

The ECC RAM is accessible to allow manually inserting faults so that the ECC checking feature can be tested. Test mode is entered by asserting the TEST bit in the ECC Control Register (Section 20.3.1.62). Once the bit is set, the ECC bits are mapped to the control packet RAM starting address A00h. The sequence to test the ECC is:

1. Write the data location of the Control Packet RAM while keeping ECC_ENA active. The ECC bits will get automatically written with the correct values in this step.
2. Enable ECC test mode by setting the TEST bit of the DMAPECR register.
3. To test single-bit error correction capability, read back one of the data written earlier, flip one of the bits and write it back. The same could be done for the ECC bits as well.
4. Similarly, to test double-bit detection capability, read back one of the data written earlier, flip two bits and write it back. The same could be done for the ECC bits as well.
5. Now read back the same data bits that were corrupted or for which the ECC was corrupted in the earlier steps 3-4.
6. Depending on the kind of corruption created, for double-bit error, read EDFLG and error address captured in DMAPAR; similarly for single-bit error, read SBERR in DMASECCCTRL and error address in DMAECCSBE.
7. The check is successful if the flag and error address are updated successfully.
8. Clear the flags (EDFLG or SBERR as applicable) and read the error address.
9. To exit the test mode, initialize the data and ECC that were corrupted earlier, back to their original values.
10. Finally, clear the TEST bit of the DMAPECR register.

NOTE: When in test mode, no ECC checking will be done when reading from ECC memory, but ECC checking will be performed on the normal memory.

This offsets in Table 20-6 must be used to run the ECC diagnostics.

Table 20-6. ECC Mapping

Offset	ECC of Control Packet (Only 9 bits are valid in the read)
A00h	0 (Lower 128 bits)
A04h	0 (Upper 128 bits)
A08h	1 (Lower 128 bits)
:	:
AFCh	31 (Upper 128 bits)

20.2.18 Initializing RAM with ECC

After power up, the RAM content including the ECC bits cannot be guaranteed. To avoid ECC failures when reading RAM, the RAM has to be initialized. The RAM can be initialized by writing known values into it. When the known value is written, the corresponding ECC bit will be automatically calculated and updated.

Another possibility to initialize the memory is to follow the Auto-Initialization of On-Chip SRAM Modules subsection in the *Architecture* chapter. The RAM will be initialized to 0. Depending on the even/odd parity selection, the parity bit will be calculated accordingly.

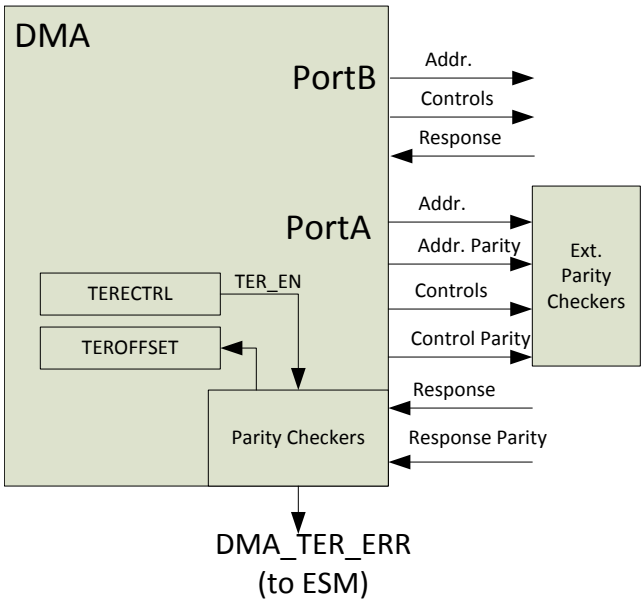
To allow for ECC calculation during initialization, the ECC functionality has to be enabled as discussed in Section 20.2.16.

Copyright © 2018, Texas Instruments Incorporated

20.2.19 Transaction Errors

DMA generates parity for all transactions and checks parity for responses to the transactions. Note that this feature is distinct from the ECC checking for the Control Packet RAM.

If a parity error is detected in these transactions and TER_EN bit in TERECTRL register is enabled, DMA will stop processing the current channel at the arbitration boundary and will update TER_ERR flag. The offset of the channel during which the parity failure was detected will get captured in the TERROFFSET register. Also, the error is indicated to the ESM module. This is shown in Figure 20-18.



Since the channel stops due to an error and likely the peripheral and the DMA are out of synchronization, it is recommended to follow the sequence below to resume the channel:

1. Read the TEROFFSET register to find the channel number causing the transaction error. The register automatically clears to 0 once read.
2. Clear the TER_ERR flag by writing 1 to the flag.
3. Disable the peripheral that triggered the DMA event.
4. Reinitialize the control packet. Note that this does not change the channel's HWCHEN bit.
5. Re-enable the peripheral to trigger the DMA event.
6. Re-enable the DMA channel (which was previously cleared by the DMA logic due to the error).

In certain cases, it is possible that DMA sets the TER_ERR flag without updating the TEROFFSET register. This occurs due to parity errors when no channels are active. The recovery sequence in this case is to clear the TER_ERR flag.

NOTE: Handling of a parity error at a system level may require additional operations that are not detailed here.

Figure 20-18. DMA Transaction Parity

NOTE: Only PortA supports transaction parity

20.3 Control Registers and Control Packets

The DMA control registers are summarized in Table 20-7. The base address for the control registers is FFFF F000h. The control packets are summarized in Table 20-8. The base address for the control packets is FFF8 0000h. Each register begins on a word boundary. All registers and control packets are accessible in 8, 16, and 32 bit.

NOTE: The register definitions are given for a full DMA module configuration (32 channels, 64 requests, 2 Ports, Dual CPU support). Writes and Reads of bits pertaining to features not included in the DMA implementation as defined in the device-specific data manual are possible without error; however, they will have no affect on device operation.

20.3.1 Global Configuration Registers

These registers control the overall behavior of the DMA controller.

20.3.1.1 Global Control Register (GCTRL)

Figure 20-19. Global Control Register (GCTRL) [offset = 00]

31															17	16
Reserved																DMA_EN
R-0																R/WP-0

15	14	13								10	9					8
Reserved	BUS_BUSY	Reserved									DEBUGMODE					
R-0	R-0	R-0									R/WP-0					

7															1	0
Reserved																DMARES
R-0																R/WP-0

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privilege mode only; -*n* = value after reset

Table 20-9. Global Control Register (GCTRL) Field Descriptions

Bit	Field	Value	Description
31-17	Reserved	0	Reads return 0. Writes have no effect.
16	DMA_EN		DMA enable bit. The configuration registers and channel control packets should be setup first before DMA_EN bit is set to one to prevent state machines from carrying out bus transactions. If DMA_EN bit is cleared in the middle of an bus transaction, the state machine will stop at an arbitration boundary.
		0	The DMA is disabled.
		1	The DMA is enabled.
15	Reserved	0	Reads return 0. Writes have no effect.
14	BUS_BUSY		This bit indicates status of DMA external AHB bus status.
		0	DMAs external bus is not busy in data transfers.
		1	DMAs external bus is busy in data transfers.
13-10	Reserved	0	Reads return 0. Writes have no effect.
9-8	DEBUGMODE		Debug Mode.
		0	Ignore suspend.
		1h	Finish current block transfer.
		2h	Finish current frame transfer.
		3h	Immediately stop at an DMA arbitration boundary and continue after suspend.
7-1	Reserved	0	Reads return 0. Writes have no effect.
0	DMARES		DMA software reset.
			Note: In the event a DMA slave does not respond, the DMA module will respond to the software reset upon reaching an arbitration boundary.
		0	Read: Software reset is disabled.
			Write: No effect.
		1	Read and write: The DMA state machine and all control registers are in software reset. Control packets are not reset when DMA software reset is active.

Bit	Field	Value	Description
31-0	PEND[*n*]		Channel pending register. Bit 0 corresponds to channel 0, bit 1 corresponds to channel 1, and so on. Reading from PEND gives the channel pending information no matter if the channel was initiated by SW or HW. Once set, it remains set even if the corresponding channel is disabled via HWCHENA or SWCHENA. The pending bit is automatically cleared for the following conditions: • At the end of a frame or a block transfer depending on how the channel is triggered as programmed in the TTYPE bit field of CHCTRL. • The control packet is modified after the pending bit is set. • A bus error occurs. • A transaction parity error occurs
		0	The corresponding channel is inactive.
		1	The corresponding channel is pending and is waiting for service.

20.3.1.3 DMA Status Register (DMASTAT)

Figure 20-21. DMA Status Register (DMASTAT) [offset = 0Ch]

31	0
STCH[31:0]	
R-0	

LEGEND: R = Read only; -*n* = value after reset

Table 20-11. DMA Status Register (DMASTAT) Field Descriptions

Bit	Field	Value	Description
31-0	STCH[*n*]		Status of DMA channels. Bit 0 corresponds to channel 0, bit 1 corresponds to channel 1, and so on.
		0	The channel is not being currently processed.
		1	The channel is currently being processed using one of the FIFOs.
			Note: The status of a channel currently being processed remains active even if emulation mode is entered or DMA is disabled via DMA_EN bit. Since there are two FIFOs, up to 2 bits can be set in this register at any given time.

31	0
HWCHENA[31:0]	
R/WP-0	

LEGEND: R/W = Read/Write; WP = Write in privilege mode only; -*n* = value after reset

Table 20-13. HW Channel Enable Set and Status Register (HWCHENAS) Field Descriptions

Bit	Field	Value	Description
31-0	HWCHENA[*n*]		Hardware channel enable bit. Bit 0 corresponds to channel 0, bit 1 corresponds to channel 1, and so on. An active hardware DMA request cannot initiate a DMA transfer unless the corresponding hardware enable bit is set. The corresponding hardware enable bit is cleared automatically for the following conditions: • At the end of a block transfer if the auto-initiation bit AIM (see CHCTRL) is not active. • If a bus error is detected for an active channel. Reading from HWCHENAS gives the status (enabled/disabled) of all channels.
		0	The corresponding channel is disabled for hardware triggering.
		1	The corresponding channel is enabled for hardware triggering.

20.3.1.6 HW Channel Enable Reset and Status Register (HWCHENAR)

Figure 20-24. HW Channel Enable Reset and Status Register (HWCHENAR) [offset = 1Ch]

20.3.1.7 SW Channel Enable Set and Status Register (SWCHENAS)

Figure 20-25. SW Channel Enable Set and Status Register (SWCHENAS) [offset = 24h]

31	0
SWCHENA[31:0]	
R/WP-0	

LEGEND: R/W = Read/Write; WP = Write in privilege mode only; -*n* = value after reset

Table 20-15. SW Channel Enable Set and Status Register (SWCHENAS) Field Descriptions

Bit	Field	Value	Description
31-0	SWCHENA[*n*]		SW channel enable bit. Bit 0 corresponds to channel 0, bit 1 corresponds to channel 1, and so on. Writing a 1 to a bit triggers a SW request on the corresponding channel to start a DMA transaction. The corresponding bit is automatically cleared by the following conditions. • The corresponding bit is cleared after one frame transfer if the TTYPE bit in Channel Control Register (CHCTRL) is programmed for frame transfer. • The corresponding bit is cleared after one block transfer if the corresponding TTYPE bit is programmed for block transfer and the auto-initiation bit is not enabled. • The control packet is modified after the pending bit is set. • The corresponding bit is cleared after one block transfer when TTYPE bit is programmed for blocks transfer and if the corresponding bit in HW channel enable register (HWCHENAS) is enabled. When a channel is enabled for both HW and SW, the state machine will initiate transfers based on the SW first. After one block transfer is complete, the corresponding bit in the SWCHENA register is then cleared. The same channel is serviced again by a HW DMA request. • The corresponding bit is cleared if a bus error is detected. • A transaction parity error occurs. Reading from SWCHENAS gives the status (enabled/disabled) of channels 0 through 31.
		0	The corresponding channel is not triggered by SW request.
		1	The corresponding channel is triggered by SW request.

20.3.1.8 SW Channel Enable Reset and Status Register (SWCHENAR)

Figure 20-26. SW Channel Enable Reset and Status Register (SWCHENAR) [offset = 2Ch]

Bit 0 corresponds to channel 0, bit 1 corresponds to channel 1, and so on. **Note: Reading from the respective interrupt channel offset register also clears the corresponding flag (see Section 20.3.1.46 and Section 20.3.1.50).** **Note: The state of the flag bit can be polled even if the corresponding interrupt enable bit is cleared.**
		0	Read: BTC interrupt of the corresponding channel is not pending. Write: No effect.
		1	Read: BTC interrupt of the corresponding channel is pending. Write: The flag is cleared.

20.3.1.42 BER Interrupt Flag Register (BERFLAG)

The BERFLAG will never be set in this device. The bus error reporting is handled by the DMA Read Imprecise Error and DMA Write Imprecise Error asserted to the ESM module directly, which are detected at the device level. See the ESM error mapping for the DMA Read/Write Imprecise Error.

R-0		R-0	R-0		R/WP-0	R/WP-0	R/WP-0

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privilege mode only; -*n* = value after reset

Table 20-58. Port Control Register (PTCRL) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24	PENDB		Transfers pending for Port B. This flag determines if transfers are ongoing on port B. The flag will be cleared if no transfers are performed. It can be used to determine if there is still data transferred while DMA_EN is cleared to 0 in GCTCRL. In this case, once all transfers are finished, the flag will be cleared to 0.
		0	No transfers are pending.
		1	Transfers are pending.
23-19	Reserved	0	Reads return 0. Writes have no effect.
18	BYB		Bypass FIFO B.
		0	FIFO B is not bypassed.
		1	FIFO B is bypassed. Writing 1 to this bit limits the FIFO depth to the size of one element. That means that after one element is read, the write-out to the destination will begin. This feature is particularly useful to minimize switching latency between channels.
			Note: This feature does not make optimal use of bus bandwidth.
17-9	Reserved	0	Reads return 0. Writes have no effect.
8	PENDA		Transfers pending for Port A. This flag determines if transfers are ongoing on port A. The flag will be cleared if no transfers are performed. It can be used to determine if there is still data transferred while DMA_EN is cleared to 0 in GCTCRL. In this case, once all transfers are finished, the flag will be cleared to 0.
		0	No transfers are pending.
		1	Transfers are pending.
7-3	Reserved	0	Reads return 0. Writes have no effect.
2	BYA		Bypass FIFO A.
		0	FIFO A is not bypassed.
		1	FIFO A is bypassed. Writing 1 to this bit limits the FIFO depth to the size of one element. That means that after one element is read, the write-out to the destination will begin. This feature is particularly useful to minimize switching latency between channels.
			Note: This feature does not make optimal use of bus bandwidth.
1	PSFRHQ		Priority scheme fix or rotate for high priority queue.
		0	Fixed priority is used.
		1	Rotation priority is used.
0	PSFRLQ		Priority scheme fix or rotate for low priority queue.
		0	The fixed priority scheme is used.
		1	The rotation priority scheme is used.

R-0	R-0	R-0	R/W1C-0

15 1	0
Reserved	DBGEN
R-0	R/WC-0

LEGEND: R/W = Read/Write; R = Read only; W1C = Write 1 to clear; -*n* = value after reset

Table 20-60. Debug Control Register (DCTRL) Field Descriptions

Bit	Field	Value	Description
31-29	Reserved	0	Reads return 0. Writes have no effect.
28-24	CHNUM	0-1Fh	Channel Number. This bit field indicates the channel number that causes the watch point to match.
23-17	Reserved	0	Reads return 0. Writes have no effect.
16	DMADBGS		DMA debug status. When a watch point is set up to watch for a unique bus address or a range of addresses is true on one of the three bus ports, then the DMA debug status bit is set to 1 and a debug request signal is asserted to the main CPU. The CPU must write a 1 to clear this bit for the DMA controller to release the debug request signal.
		0	Read: No watch point condition is detected. Write: No effect.
		1	Read: The watch point condition is detected. Write: The bit is cleared.
15-1	Reserved	0	Reads return 0. Writes have no effect.
0	DBGEN		Debug Enable. **Note: This bit can only be set when using a debugger.** **Note: This bit is reset when Test reset ($\overline{\text{TRST}}$) is low.**
		0	Debug is disabled.
		1	The watch point checking logics is enabled.

20.3.1.54 Watch Point Register (WPR)

Figure 20-71. Watch Point Register (WPR) [offset = 184h]

31	0
WP	
R/W-0	

LEGEND: R/W = Read/Write; -*n* = value after reset

Table 20-61. Watch Point Register (WPR) Field Descriptions

Bit	Field	Description
31-0	WP	Watch point. **Note: These bits can only be set when using a debugger.** This register is only reset by a test reset ($\overline{\text{TRST}}$). A 32-bit address can be programmed into this register as a watch point. This register is used with the watch mask register (WMR). When the DBGEN bit in the DCTRL register is set and a unique address or a range of addresses are detected on the AHB address bus of Port B, a debug request signal is sent to the ARM CPU. The state machine of the port in which the watch point condition is true is frozen.

R-0																R/WP-0

15							9	8	7			4	3			0
Reserved								TEST	Reserved				ECC_ENA			
R-0								R/WP-0	R-0				R/WP-5h			

LEGEND: R/W = Read/Write; R = Read only; WP = Write in privilege mode only; -*n* = value after reset

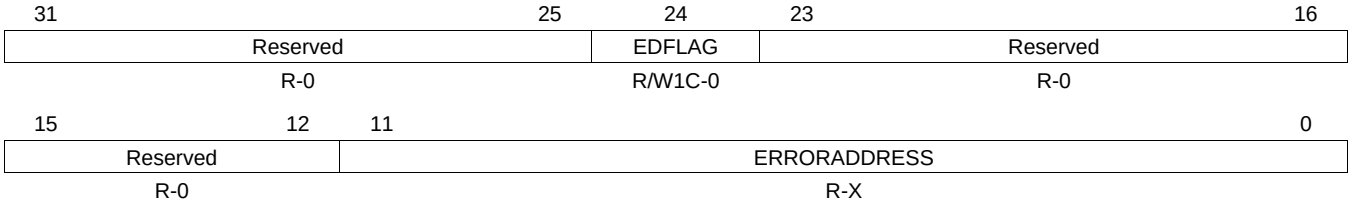

Table 20-69. ECC Control Register (DMAPECR) Field Descriptions

Bit	Field	Value	Description
31-17	Reserved	0	Reads return 0. Writes have no effect.
16	ERRA		Error action.
		0	If a parity error is detected on control packet x (x = 0, 1, ... n), then the enable/disable state of control packet x remains unchanged.
		1	If a parity error is detected on control packet x (x = 0, 1, ...n), then the DMA controller is disabled immediately. If a frame on control packet x is processed at the time the parity error is detected, then remaining elements of this frame will not be transferred anymore. The DMA will be disabled regardless of whether the error was detected during a read to the control packet RAM performed by the DMA state machine or by a different master.
15-9	Reserved	0	Reads return 0. Writes have no effect.
8	TEST		When this bit is set, the parity bits are memory-mapped to make them accessible by the CPU.
		0	The parity bits are not memory-mapped.
		1	The parity bits are memory-mapped.
7-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	ECC_ENA		ECC enable. This bit field enables or disables the ECC check on read operations and the ECC calculation on write operations. If ECC checking is enabled and an ECC double-bit error is detected the DMA_UERR signal is activated.
		5h	The ECC check is disabled.
		All other values	The ECC check is enabled.
			Note: It is recommended to write Ah to enable ECC check, to guard against soft error from flipping ECC_ENA to a disable state.

Copyright © 2018, Texas Instruments Incorporated

20.3.1.63 DMA ECC Error Address Register (DMAPAR)

Figure 20-80. DMA ECC Error Address Register (DMAPAR) [offset = 1ACh]

LEGEND: R/W = Read/Write; R = Read only; W1C = Write 1 to clear; X= value is undefined; -*n* = value after reset

Table 20-70. DMA ECC Error Address Register (DMAPAR) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24	EDFLAG		ECC Error Detection Flag. This flag indicates if an ECC error occurred on reading DMA Control packet RAM.
		0	Read: No error occurred. Write: No effect.
		1	Read: Error detected and the address is captured in DMAPAR's ERROR_ADDRESS field. Write: Clears the bit.
23-12	Reserved	0	Reads return 0. Writes have no effect.
11-0	ERRORADDRESS	0-FFFh	Error address. These bits hold the address of the first ECC error generated in the RAM. This error address is frozen from being updated until it is read by the CPU. During emulation mode when SUSPEND is high, this address is frozen even when read. **Note: The error address register will not be reset by PORRST nor by any other reset source.**

Table 20-71. DMA Memory Protection Control Register 1 (DMAMPCTRL1) Field Descriptions (continued)

Bit	Field	Value	Description
15-13	Reserved	0	Reads return 0. Writes have no effect.
12	INT1AB		Interrupt assignment of region 1 to Group A or Group B.
		0	The interrupt is routed to the VIM (Group A).
		1	The interrupt is routed to the second CPU (Group B).
11	INT1ENA		Interrupt enable of region 1.
		0	The interrupt is disabled.
		1	The interrupt is enabled.
10-9	REG1AP		Region 1 access permission. These bits determine the access permission for region 3.
		0	All accesses are allowed.
		1h	Read only accesses are allowed.
		2h	Write only accesses are allowed.
		3h	No accesses are allowed.
8	REG1ENA		Region 1 enable.
		0	The region is disabled (no address checking done).
		1	The region is enabled (address and access permission checking done).
7-5	Reserved	0	Reads return zeros and writes have no effect.
4	INT0AB		Interrupt assignment of region 0 to Group A or Group B.
		0	The interrupt is routed to the VIM (Group A).
		1	The interrupt is routed to the second CPU (Group B).
3	INT0ENA		Interrupt enable of region 0.
		0	The interrupt is disabled.
		1	The interrupt is enabled.
2-1	REG0AP		Region 0 access permission. These bits determine the access permission for region 0.
		0	All accesses are allowed.
		1h	Read only accesses are allowed.
		2h	Write only accesses are allowed.
		3h	No accesses are allowed.
0	REG0ENA		Region 0 enable.
		0	The region is disabled (no address checking done).
		1	The region is enabled (address and access permission checking done).

11-0	ERRORADDRESS	0-FFFh	The DMA RAM address (offset from base address word aligned) of the ECC error location. This register gives the address of the first encountered single-bit ECC error since the SBERR flag has been clear. Subsequent single-bit ECC errors will not update this register until the SBERR flag has been cleared. This register is valid only when the SBERR flag is set. Read: This register clears to 0x0000 once it is read by the CPU. For a read issued by the debugger this address is frozen even when read. Write: No effect **Note: The error address register will not be reset by PORRST nor by any other reset source.**

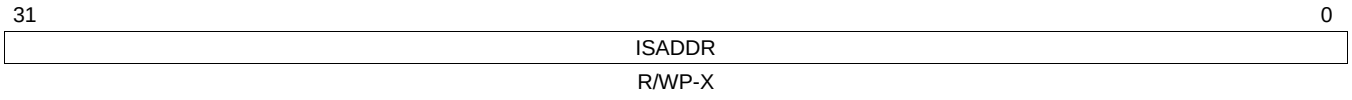
20.3.2 Channel Configuration



The channel configuration is defined by the channel control packet: channel control, transfer count, offset values, source/destination address.

- It is stored in local RAM, which is protected by parity.
- Each control packet contains a total of nine fields.
- The first six fields are programmable, while the last three fields are read only.
- The RAM is accessible by queue A and queue B state machines as well as CPU.
- When there are simultaneous accesses, the priority is resolved in a fixed priority scheme with the CPU having the highest priority.

All the control packets look the same. Following, there is the detailed layout of these registers shown for control packet 0.

20.3.2.1 Initial Source Address Register (ISADDR)

External Memory Interface (EMIF)

This chapter describes the external memory Interface (EMIF).

Topic **Page**

21.1 Introduction **794**
21.2 EMIF Module Architecture **796**
21.3 EMIF Registers **828**
21.4 Example Configuration **840**

Copyright © 2018, Texas Instruments Incorporated

21.1 Introduction

21.1.1 Purpose of the Peripheral

This EMIF memory controller is compliant with the JESD21-C SDR SDRAM memories utilizing a 16-bit data bus. The purpose of this EMIF is to provide a means for the CPU to connect to a variety of external devices including:

- Single data rate (SDR) SDRAM
- Asynchronous devices including NOR Flash and SRAM

The most common use for the EMIF is to interface with both a flash device and an SDRAM device simultaneously. Section 21.4 contains an example of operating the EMIF in this configuration.

21.1.2 Features

The EMIF includes many features to enhance the ease and flexibility of connecting to external SDR SDRAM and asynchronous devices.

21.1.2.1 Asynchronous Memory Support

EMIF supports asynchronous:

- SRAM memories
- NOR Flash memories

The EMIF data bus width is up to 16 bits and there are up to 22 address lines. There is an external wait input that allows slower asynchronous memories to extend the memory access. The EMIF module supports up to 3 chip selects (EMIF_nCS[4:2]). Each chip select has the following individually programmable attributes:

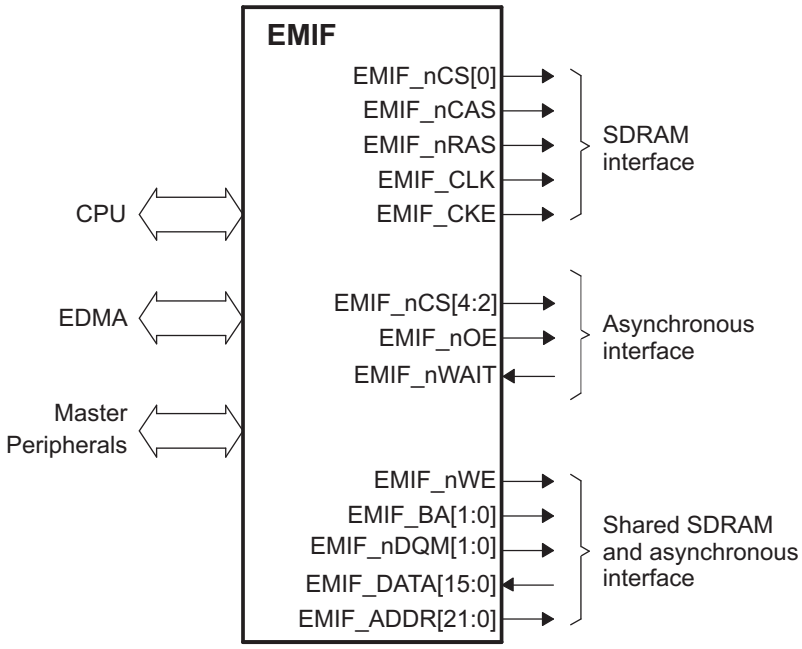
- Data Bus Width
- Read cycle timings: setup, hold, strobe
- Write cycle timings: setup, hold, strobe
- Bus turn-around time
- Extended Wait Option with Programmable Timeout
- Select Strobe option

21.1.2.2 Synchronous DRAM Memory Support

The EMIF module supports 16-bit SDRAM in addition to the asynchronous memories listed in Section 21.1.2.1. It has a single SDRAM chip select (EMIF_nCS[0]). SDRAM configurations that are supported are:

- One, Two and Four Bank SDRAM devices
- Devices with Eight, Nine, Ten, and Eleven Column Address
- CAS Latency of two or three clock cycles
- 16-bit Data Bus Width
- 3.3V LVCMOS Interface

Additionally, the EMIF supports placing the SDRAM in Self-Refresh and Powerdown modes. Self-refresh mode allows the SDRAM to be put in a low-power state while still retaining memory contents; since the SDRAM will continue to refresh itself even without clocks from the microcontroller. Powerdown mode achieves even lower power, except the microcontroller must periodically wake up and issue refreshes if data retention is required.



Note that the EMIF module does not support Mobile SDRAM devices.

Copyright © 2018, Texas Instruments Incorporated

21.1.3 Functional Block Diagram

Figure 21-1 illustrates the connections between the EMIF and its internal requesters, along with the external EMIF pins. Section 21.2.2 contains a description of the entities internal to the SoC that can send requests to the EMIF, along with their prioritization. Section 21.2.3 describes the EMIF external pins and summarizes their purpose when interfacing with SDRAM and asynchronous devices.

Figure 21-1. EMIF Functional Block Diagram

Copyright © 2018, Texas Instruments Incorporated

21.2 EMIF Module Architecture

This section provides details about the architecture and operation of the EMIF. Both, SDRAM and asynchronous Interface are covered, along with other system-related issues such as clock control.

21.2.1 EMIF Clock Control

The EMIF clock is output on the EMIF_CLK pin and should be used when interfacing to external SDRAM devices. The EMIF module gets the VCLK3 clock domain as the input. This clock domain is running at half the frequency of the main oscillator by default, that is, between 2.5MHz to 10MHz. The VCLK3 frequency is divided down from the HCLK domain frequency by a programmable divider (/1 to /16). Refer the Architecture chapter of the device technical reference manual for more information on configuring the VCLK3 domain frequency.

21.2.2 EMIF Requests

Different sources within the SoC can make requests to the EMIF. These requests consist of accesses to SDRAM memory, asynchronous memory, and EMIF registers. The EMIF can process only one request at a time. Therefore a high performance crossbar switch exists within the SoC to provide prioritized requests from the different sources to the EMIF. The sources are:

1. CPU
2. DMA
3. Other master peripherals

If a request is submitted from two or more sources simultaneously, the crossbar switch will forward the highest priority request to the EMIF first. Upon completion of a request, the crossbar switch again evaluates the pending requests and forwards the highest priority pending request to the EMIF.

When the EMIF receives a request, it may or may not be immediately processed. In some cases, the EMIF will perform one or more auto refresh cycles before processing the request. For details on the EMIF's internal arbitration between performing requests and performing auto refresh cycles, see Section 21.2.13.

21.2.3 EMIF Signal Descriptions

This section describes the function of each of the EMIF signals.

Table 21-1. EMIF Pins Used to Access Both SDRAM and Asynchronous Memories

Pins(s)	I/O	Description
EMIF_DATA[15:0]	I/O	**EMIF data bus.**
EMIF_ADDR[21:0]	O	**EMIF address bus.** When interfacing to an SDRAM device, these pins are primarily used to provide the row and column address to the SDRAM. The mapping from the internal program address to the external values placed on these pins can be found in Table 21-13. EMIF_A[10] is also used during the PRE command to select which banks to deactivate. When interfacing to an asynchronous device, these pins are used in conjunction with the EMIF_BA pins to form the address that is sent to the device. The mapping from the internal program address to the external values placed on these pins can be found in Section 21.2.6.1.
EMIF_BA[1:0]	O	**EMIF bank address.** When interfacing to an SDRAM device, these pins are used to provide the bank address inputs to the SDRAM. The mapping from the internal program address to the external values placed on these pins can be found inTable 21-13. When interfacing to an asynchronous device, these pins are used in conjunction with the EMIF_A pins to form the address that is sent to the device. The mapping from the internal program address to the external values placed on these pins can be found in Section 21.2.6.1.
EMIF_nDQM[1:0]	O	**Active-low byte enables.** When interfacing to SDRAM, these pins are connected to the DQM pins of the SDRAM to individually enable/disable each of the bytes in a data access. When interfacing to an asynchronous device, these pins are connected to byte enables. See Section 21.2.6 for details.

Copyright © 2018, Texas Instruments Incorporated

Table 21-1. EMIF Pins Used to Access Both SDRAM and Asynchronous Memories (continued)

Pins(s)	I/O	Description
EMIF_nWE	O	**Active-low write enable.** When interfacing to SDRAM, this pin is connected to the nWE pin of the SDRAM and is used to send commands to the device. When interfacing to an asynchronous device, this pin provides a signal which is active-low during the strobe period of an asynchronous write access cycle.

Table 21-2. EMIF Pins Specific to SDRAM

Pin(s)	I/O	Description
EMIF_nCS[0]	O	**Active-low chip enable pin for SDRAM devices.** This pin is connected to the chip-select pin of the attached SDRAM device and is used for enabling/disabling commands. By default, the EMIF keeps this SDRAM chip select active, even if the EMIF is not interfaced with an SDRAM device. This pin is deactivated when accessing the asynchronous memory bank and is reactivated on completion of the asynchronous access.
EMIF_nRAS	O	**Active-low row address strobe pin.** This pin is connected to the nRAS pin of the attached SDRAM device and is used for sending commands to the device.
EMIF_nCAS	O	**Active-low column address strobe pin.** This pin is connected to the nCAS pin of the attached SDRAM device and is used for sending commands to the device.
EMIF_CKE	O	**Clock enable pin.** This pin is connected to the CKE pin of the attached SDRAM device and is used for issuing the SELF REFRESH command which places the device in self refresh mode. See Section 21.2.5.7 for details.
EMIF_CLK	O	**SDRAM clock pin.** This pin is connected to the CLK pin of the attached SDRAM device. See Section 21.2.1 for details on the clock signal.

Table 21-3. EMIF Pins Specific to Asynchronous Memory

Pin(s)	I/O	Description
EMIF_nCS[4:2]	O	**Active-low chip enable pins for asynchronous devices.** These pins are meant to be connected to the chip-select pins of the attached asynchronous device. These pins are active only during accesses to the asynchronous memory.
EMIF_nWAIT	I	**Wait input with programmable polarity.** A connected asynchronous device can extend the strobe period of an access cycle by asserting the EMIF_nWAIT input to the EMIF as described in Section 21.2.6.6. To enable this functionality, the EW bit in the asynchronous 1 configuration register (CE2CFG) must be set to 1. In addition, the WP0 bit in CE2CFG must be configured to define the polarity of the EMIF_nWAIT pin.
EMIF_nOE	O	**Active-low pin enable for asynchronous devices.** This pin provides a signal which is active-low during the strobe period of an asynchronous read access cycle.

21.2.4 EMIF Signal Multiplexing Control

Several EMIF signals are multiplexed with other functions on this microcontroller. Please refer to the I/O Multiplexing Module chapter of the technical reference manual for more information on how to enable the output of these EMIF signals.

Copyright © 2018, Texas Instruments Incorporated

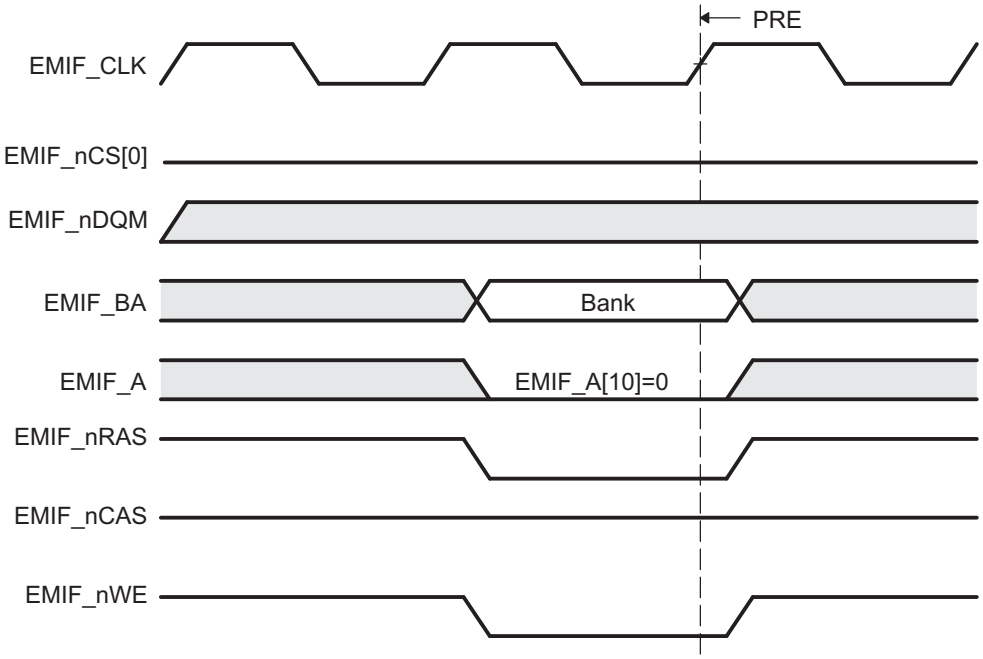
21.2.5 SDRAM Controller and Interface

The EMIF can gluelessly interface to most standard SDR SDRAM devices and supports such features as self refresh mode and prioritized refresh. In addition, it provides flexibility through programmable parameters such as the refresh rate, CAS latency, and many SDRAM timing parameters. The following sections include details on how to Interface and properly configure the EMIF to perform read and write operations to externally connected SDR SDRAM devices. Also, Section 21.4 provides a detailed example of interfacing the EMIF to a common SDRAM device.

21.2.5.1 SDRAM Commands

The EMIF supports the SDRAM commands described in Table 21-4. Table 21-5 shows the truth table for the SDRAM commands, and an example timing waveform of the PRE command is shown in Figure 21-2. EMIF_A[10] is pulled low in this example to deactivate only the bank specified by the EMIF_BA pins.

Table 21-4. EMIF SDRAM Commands



Command	Function
PRE	**Precharge.** Depending on the value of EMIF_A[10], the PRE command either deactivates the open row in all banks (EMIF_A[10] = 1) or only the bank specified by the EMIF_BA[1:0] pins (EMIF_A[10] = 0).
ACTV	**Activate**. The ACTV command activates the selected row in a particular bank for the current access.
READ	**Read.** The READ command outputs the starting column address and signals the SDRAM to begin the burst read operation. Address EMIF_A[10] is always pulled low to avoid auto precharge. This allows for better bank interleaving performance.
WRT	**Write.** The WRT command outputs the starting column address and signals the SDRAM to begin the burst write operation. Address EMIF_A[10] is always pulled low to avoid auto precharge. This allows for better bank interleaving performance.
BT	**Burst terminate**. The BT command is used to truncate the current read or write burst request.
LMR	**Load mode register**. The LMR command sets the mode register of the attached SDRAM devices and is only issued during the SDRAM initialization sequence described in Section 21.2.5.4.
REFR	**Auto refresh**. The REFR command signals the SDRAM to perform an auto refresh according to its internal address.
SLFR	**Self refresh**. The self refresh command places the SDRAM into self refresh mode, during which it provides its own clock signal and auto refresh cycles.
NOP	**No operation**. The NOP command is issued during all cycles in which one of the above commands is not issued.

Table 21-5. Truth Table for SDRAM Commands

SDRAM Pins:	CKE	nCS	nRAS	nCAS	nWE	BA[1:0]	A[12:11]	A[10]	A[9:0]

21.2.5.2 Interfacing to SDRAM

The EMIF supports a glueless interface to SDRAM devices with the following characteristics:

- Pre-charge bit is A[10]
- The number of column address bits is 8, 9, 10, or 11.
- The number of row address bits is 13, 14, 15, or 16.
- The number of internal banks is 1, 2, or 4.

Figure 21-3 shows an interface between the EMIF and a 2M × 16 × 4 bank SDRAM device, and Figure 21-4 shows an interface between the EMIF and a 512K × 16 × 2 bank SDRAM device. For devices supporting 16-bit interface, refer to Table 21-6 for list of commonly-supported SDRAM devices and the required connections for the address pins.

21.2.5.3 SDRAM Configuration Registers

The operation of the EMIF's SDRAM interface is controlled by programming the appropriate configuration registers. This section describes the purpose and function of each configuration register, but Section 21.3 should be referred for a more detailed description of each register, including the default registers values and bit-field positions. The following tables list the four such configuration registers, along with a description of each of their programmable fields.

NOTE: Writing to any of the fields: NM, CL, IBANK, and PAGESIZE in the SDRAM configuration register (SDCR) causes the EMIF to abandon whatever it is currently doing and trigger the SDRAM initialization procedure described in Section 21.2.5.4.

Table 21-7. Description of the SDRAM Configuration Register (SDCR)

Parameter	Description
SR	This bit controls entering and exiting of the Self-Refresh mode. The field should be written using a byte-write to the upper byte of SDCR to avoid triggering the SDRAM initialization sequence.
PD	This bit controls entering and exiting of the Power down mode. The field should be written using a byte-write to the upper byte of SDCR to avoid triggering the SDRAM initialization sequence. If both SR and PD bits are set, the EMIF will go into Self Refresh.
PDWR	Perform refreshes during Power Down. Writing a 1 to this bit will cause the EMIF to exit the power down state and issue an AUTO REFRESH command every time Refresh May level is set. The field should be written using a byte-write to the upper byte of SDCR to avoid triggering the SDRAM initialization sequence. This bit should be set along with PD when entering power-down mode.
NM	**Narrow Mode.** This bit defines the width of the data bus between the EMIF and the attached SDRAM device. When set to 1, the data bus is set to 16-bits. When set to 0, the data bus is set to 32-bits. This bit must always be set to 1.
CL	**CAS latency.** This field defines the number of clock cycles between when an SDRAM issues a READ command and when the first piece of data appears on the bus. The value in this field is sent to the attached SDRAM device via the LOAD MODE REGISTER command during the SDRAM initialization procedure as described in Section 21.2.5.4. Only, values of 2h (CAS latency = 2) and 3h (CAS latency = 3) are supported and should be written to this field. A 1 must be simultaneously written to the BIT11_9LOCK bit field of SDCR in order to write to the CL bit field.
IBANK	**Number of Internal SDRAM Banks.** This field defines the number of banks inside the attached SDRAM devices in the following way: • When IBANK = 0, 1 internal bank is used • When IBANK = 1h, 2 internal banks are used • When IBANK = 2h, 4 internal banks are used This field value affects the mapping of logical addresses to SDRAM row, column, and bank addresses. See Section 21.2.5.11 for details.
PAGESIZE	**Page Size.** This field defines the internal page size of the attached SDRAM devices in the following way: • When PAGESIZE = 0, 256-word pages are used • When PAGESIZE = 1h, 512-word pages are used • When PAGESIZE = 2h, 1024-word pages are used • When PAGESIZE = 3h, 2048-word pages are used This field value affects the mapping of logical addresses to SDRAM row, column, and bank addresses. See Section 21.2.5.11 for details.

Table 21-8. Description of the SDRAM Refresh Control Register (SDRCR)

Parameter	Description
RR	**Refresh Rate**. This field controls the rate at which attached SDRAM devices will be refreshed. The following equation can be used to determine the required value of RR for an SDRAM device: • RR = f_{EMIF_CLK} / (Required SDRAM Refresh Rate) More information about the operation of the SDRAM refresh controller can be found in Section 21.2.5.6.

Copyright © 2018, Texas Instruments Incorporated

Table 21-9. Description of the SDRAM Timing Register (SDTIMR)

Parameter	Description
T_RFC T_RP T_RCD T_WR T_RAS T_RC T_RRD	**SDRAM Timing Parameters.** These fields configure the EMIF to comply with the AC timing requirements of the attached SDRAM devices. This allows the EMIF to avoid violating SDRAM timing constraints and to more efficiently schedule its operations. More details about each of these parameters can be found in the register description in Section 21.3.6. These parameters should be set to satisfy the corresponding timing requirements found in the SDRAM's datasheet.

Table 21-10. Description of the SDRAM Self Refresh Exit Timing Register (SDSRETR)

Parameter	Description
T_XS	**Self Refresh Exit Parameter.** The T_XS field of this register informs the EMIF about the minimum number of EMIF_CLK cycles required between exiting Self Refresh and issuing any command. This parameter should be set to satisfy the t_{XSR} value for the attached SDRAM device.

21.2.5.4 SDRAM Auto-Initialization Sequence

The EMIF automatically performs an SDRAM initialization sequence, regardless of whether it is interfaced to an SDRAM device, when either of the following two events occur:

- The EMIF comes out of reset. No memory accesses to the SDRAM and Asynchronous interfaces are performed until this auto-initialization is complete.
- A write is performed to any of the three least significant bytes of the SDRAM configuration register (SDCR)

An SDRAM initialization sequence consists of the following steps:

1. If the initialization sequence is activated by a write to SDCR, and if any of the SDRAM banks are open, the EMIF issues a PRE command with EMIF_A[10] held high to indicate all banks. This is done so that the maximum ACTV to PRE timing for an SDRAM is not violated.
2. The EMIF drives EMIF_CKE high and begins continuously issuing NOP commands until eight SDRAM refresh intervals have elapsed. An SDRAM refresh interval is equal to the value of the RR field of SDRAM refresh control register (SDRCR), divided by the frequency of EMIF_CLK (RR/f_{EMIF_CLK}). This step is used to avoid violating the Power-up constraint of most SDRAM devices that requires 200 μs (sometimes 100 μs) between receiving stable Vdd and CLK and the issuing of a PRE command. Depending on the frequency of EMIF_CLK, this step may or may not be sufficient to avoid violating the SDRAM constraint. See Section 21.2.5.5 for more information.
3. After the refresh intervals have elapsed, the EMIF issues a PRE command with EMIF_A[10] held high to indicate all banks.
4. The EMIF issues eight AUTO REFRESH commands.
5. The EMIF issues the LMR command with the EMIF_A[9:0] pins set as described in Table 21-11.
6. Finally, the EMIF performs a refresh cycle, which consists of the following steps:
   a. Issuing a PRE command with EMIF_A[10] held high if any banks are open
   b. Issuing an REF command

Copyright © 2018, Texas Instruments Incorporated

Table 21-11. SDRAM LOAD MODE REGISTER Command

EMIF_A[9:7]	EMIF_A[6:4]	EMIF_A[3]	EMIF_A[2:0]
0 (Write bursts are of the programmed burst length in EMIF_A[2:0])	These bits control the CAS latency of the SDRAM and are set according to CL field in the SDRAM configuration register (SDCR) as follows: • If CL = 2, EMIF_A[6:4] = 2h (CAS latency = 2) • If CL = 3, EMIF_A[6:4] = 3h (CAS latency = 3)	0 (Sequential Burst Type. Interleaved Burst Type not supported)	These bits control the burst length of the SDRAM and are set according to the NM field in the SDRAM configuration register (SDCR) as follows: • If NM = 0, EMIF_A[2:0] = 2h (Burst Length = 4) • If NM = 1, EMIF_A[2:0] = 3h (Burst Length = 8)

21.2.5.5 SDRAM Configuration Procedure

There are two different SDRAM configuration procedures. Although EMIF automatically performs the SDRAM initialization sequence described in Section 21.2.5.4 when coming out of reset, it is recommended to follow one of the procedures listed below before performing any EMIF memory requests. Procedure A should be followed if it is determined that the SDRAM Power-up constraint was not violated during the SDRAM Auto-Initialization Sequence detailed in Section 21.2.5.4 on coming out of Reset. The SDRAM Power-up constraint specifies that 200 μs (sometimes 100 μs) should exist between receiving stable Vdd and CLK and the issuing of a PRE command. Procedure B should be followed if the SDRAM Power-up constraint was violated. The 200 μs (100 μs) SDRAM Power-up constraint will be violated if the frequency of EMIF_CLK is greater than 50 MHz (100 MHz for 100 μs SDRAM power-up constraint) during SDRAM Auto-Initialization Sequence. Procedure B should be followed if there is any doubt that the Power-up constraint was not met.

Procedure A — Following is the procedure to be followed if the SDRAM Power-up constraint was NOT violated:

1. Place the SDRAM into Self-Refresh Mode by setting the SR bit of SDCR to 1. A byte-write to the upper byte of SDCR should be used to avoid restarting the SDRAM Auto-Initialization Sequence described in Section 21.2.5.4. The SDRAM should be placed into Self-Refresh mode when changing the frequency of EMIF_CLK to avoid incurring the 200 μs Power-up constraint again.
2. Configure the desired EMIF_CLK clock frequency. The frequency of the memory clock must meet the timing requirements in the SDRAM manufacturer's documentation and the timing limitations shown in the electrical specifications of the device datasheet.
3. Remove the SDRAM from Self-Refresh Mode by clearing the SR bit of SDCR to 0. A byte-write to the upper byte of SDCR should be used to avoid restarting the SDRAM Auto-Initialization Sequence described in Section 21.2.5.4.
4. Program SDTIMR and SDSRETR to satisfy the timing requirements for the attached SDRAM device. The timing parameters should be taken from the SDRAM datasheet.
5. Program the RR field of SDRCR to match that of the attached device's refresh interval. See Section 21.2.5.6.1 details on determining the appropriate value.
6. Program SDCR to match the characteristics of the attached SDRAM device. This will cause the auto-initialization sequence in Section 21.2.5.4 to be re-run. This second initialization generally takes much less time due to the increased frequency of EMIF_CLK.

Procedure B — Following is the procedure to be followed if the SDRAM Power-up constraint was violated:

1. Configure the desired EMIF_CLK clock frequency. The frequency of the memory clock must meet the timing requirements in the SDRAM manufacturer's documentation and the timing limitations shown in the electrical specifications of the device datasheet.
2. Program SDTIMR and SDSRETR to satisfy the timing requirements for the attached SDRAM device. The timing parameters should be taken from the SDRAM datasheet.
3. Program the RR field of SDRCR such that the following equation is satisfied: $(RR \times 8)/(f_{EMIF\_CLK}) >$ 200 μs (sometimes 100 μs). For example, an EMIF_CLK frequency of 100 MHz would require setting RR to 2501 (9C5h) or higher to meet a 200 μs constraint.

Copyright © 2018, Texas Instruments Incorporated

4. Program SDCR to match the characteristics of the attached SDRAM device. This will cause the auto-initialization sequence in Section 21.2.5.4 to be re-run with the new value of RR.
5. Perform a read from the SDRAM to assure that step 5 of this procedure will occur after the initialization process has completed. Alternatively, wait for 200 μs instead of performing a read.
6. Finally, program the RR field to match that of the attached device's refresh interval. See Section 21.2.5.6.1 details on determining the appropriate value.

After following the above procedure, the EMIF is ready to perform accesses to the attached SDRAM device. See Section 21.4 for an example of configuring the SDRAM interface.

21.2.5.6 EMIF Refresh Controller

An SDRAM device requires that each of its rows be refreshed at a minimum required rate. The EMIF can meet this constraint by performing auto refresh cycles at or above this required rate. An auto refresh cycle consists of issuing a PRE command to all banks of the SDRAM device followed by issuing a REFR command. To inform the EMIF of the required rate for performing auto refresh cycles, the RR field of the SDRAM refresh control register (SDRCR) must be programmed. The EMIF will use this value along with two internal counters to automatically perform auto refresh cycles at the required rate. The auto refresh cycles cannot be disabled, even if the EMIF is not interfaced with an SDRAM. The remainder of this section details the EMIF's refresh scheme and provides an example for determining the appropriate value to place in the RR field of SDRCR.

The two counters used to perform auto-refresh cycles are a 13-bit refresh interval counter and a 4-bit refresh backlog counter. At reset and upon writing to the RR field, the refresh interval counter is loaded with the value from RR field and begins decrementing, by one, each EMIF clock cycle. When the refresh interval counter reaches zero, the following actions occur:

- The refresh interval counter is reloaded with the value from the RR field and restarts decrementing.
- The 4-bit refresh backlog counter increments unless it has already reached its maximum value.

The refresh backlog counter records the number of auto refresh cycles that the EMIF currently has outstanding. This counter is decremented by one each time an auto refresh cycle is performed and incremented by one each time the refresh interval counter expires. The refresh backlog counter saturates at the values of 0000b and 1111b. The EMIF uses the refresh backlog counter to determine the urgency with which an auto refresh cycle should be performed. The four levels of urgency are described in Table 21-12. This refresh scheme allows the required refreshes to be performed with minimal impact on access requests.

Table 21-12. Refresh Urgency Levels

Urgency Level	Refresh Backlog Counter Range	Action Taken
Refresh May	1-3	An auto-refresh cycle is performed only if the EMIF has no requests pending and none of the SDRAM banks are open.
Refresh Release	4-7	An auto-refresh cycle is performed if the EMIF has no requests pending, regardless of whether any SDRAM banks are open.
Refresh Need	8-11	An auto-refresh cycle is performed at the completion of the current access unless there are read requests pending.
Refresh Must	12-15	Multiple auto-refresh cycles are performed at the completion of the current access until the Refresh Release urgency level is reached. At that point, the EMIF can begin servicing any new read or write requests.

21.2.5.6.1 Determining the Appropriate Value for the RR Field

The value that should be programmed into the RR field of SDRCR can be calculated by using the frequency of the EMIF_CLK signal (f_{EMIF_CLK}) and the required refresh rate of the SDRAM ($f_{Refresh}$). The following formula can be used:

$RR = f_{EMIF\_CLK} / f_{Refresh}$

The SDRAM datasheet often communicates the required SDRAM Refresh Rate in terms of the number of REFR commands required in a given time interval. The required SDRAM Refresh Rate in the formula above can therefore be calculated by dividing the number of required cycles per time interval (n_{cycles}) by the time interval given in the datasheet ($t_{Refresh\ Period}$) :

$f_{Refresh} = n_{cycles} / t_{Refresh\ Period}$

Combining these formulas, the value that should be programmed into the RR field can be computed as:

$RR = f_{EMIF\_CLK} \times t_{Refresh\ Period} / n_{cycles}$

The following example illustrates calculating the value of RR. Given that:

- f_{EMIF_CLK} = 100 MHz (frequency of the EMIF clock)
- $t_{Refresh\ Period}$ = 64 ms (required refresh interval of the SDRAM)
- n_{cycles} = 8192 (number of cycles in a refresh interval for the SDRAM)

RR can be calculated as:

RR = 100 MHz × 64 ms/8192

RR = 781.25

RR = 782 cycles = 30Eh cycles

21.2.5.7 Self-Refresh Mode

The EMIF can be programmed to enter the self-refresh state by setting the SR bit of SDCR to 1. This will cause the EMIF to issue the SLFR command after completing any outstanding SDRAM access requests and clearing the refresh backlog counter by performing one or more auto refresh cycles. This places the attached SDRAM device into self-refresh mode in which it consumes a minimal amount of power while performing its own refresh cycles. The SR bit should be set and cleared using a byte-write to the upper byte of the SDRAM configuration register (SDCR) to avoid triggering the SDRAM initialization sequence.

While in the self-refresh state, the EMIF continues to service asynchronous bank requests and register accesses as normal, with one caveat. The EMIF will not park the data bus following a read to asynchronous memory while in the self-refresh state. Instead, the EMIF tri-states the data bus. Therefore, it is not recommended to perform asynchronous read operations while the EMIF is in the self-refresh state, in order to prevent floating inputs on the data bus. More information about data bus parking can be found in Section 21.2.7.

The EMIF will exit from the self-refresh state if either of the following events occur:

- The SR bit of SDCR is cleared to 0.
- An SDRAM accesses is requested.

The EMIF exits from the self-refresh state by driving EMIF_CKE high and performing an auto refresh cycle.

The attached SDRAM device should also be placed into Self-Refresh Mode when changing the frequency of EMIF_CLK. If the frequency of EMIF_CLK changes while the SDRAM is not in Self-Refresh Mode, Procedure B in Section 21.2.5.5 should be followed to reinitialize the device.

Copyright © 2018, Texas Instruments Incorporated

21.2.5.8 Power Down Mode

To support low-power modes, the EMIF can be requested to issue a POWER DOWN command to the SDRAM by setting the PD bit in the SDRAM configuration register (SDCR). When this bit is set, the EMIF will continue normal operation until all outstanding memory access requests have been serviced and the SDRAM refresh backlog (if there is one) has been cleared. At this point the EMIF will enter the power-down state. Upon entering this state, the EMIF will issue a POWER DOWN command (same as a NOP command but driving EMIF_CKE low on the same cycle). The EMIF then maintains EMIF_CKE low until it exits the power-down state.

Since the EMIF services the refresh backlog before it enters the power-down state, all internal banks of the SDRAM are closed (precharged) prior to issuing the POWER DOWN command. Therefore, the EMIF only supports Precharge Power Down. The EMIF does not support Active Power Down, where internal banks of the SDRAM are open (active) before the POWER DOWN command is issued.

During the power-down state, the EMIF services the SDRAM, asynchronous memory, and register accesses as normal, returning to the power-down state upon completion.

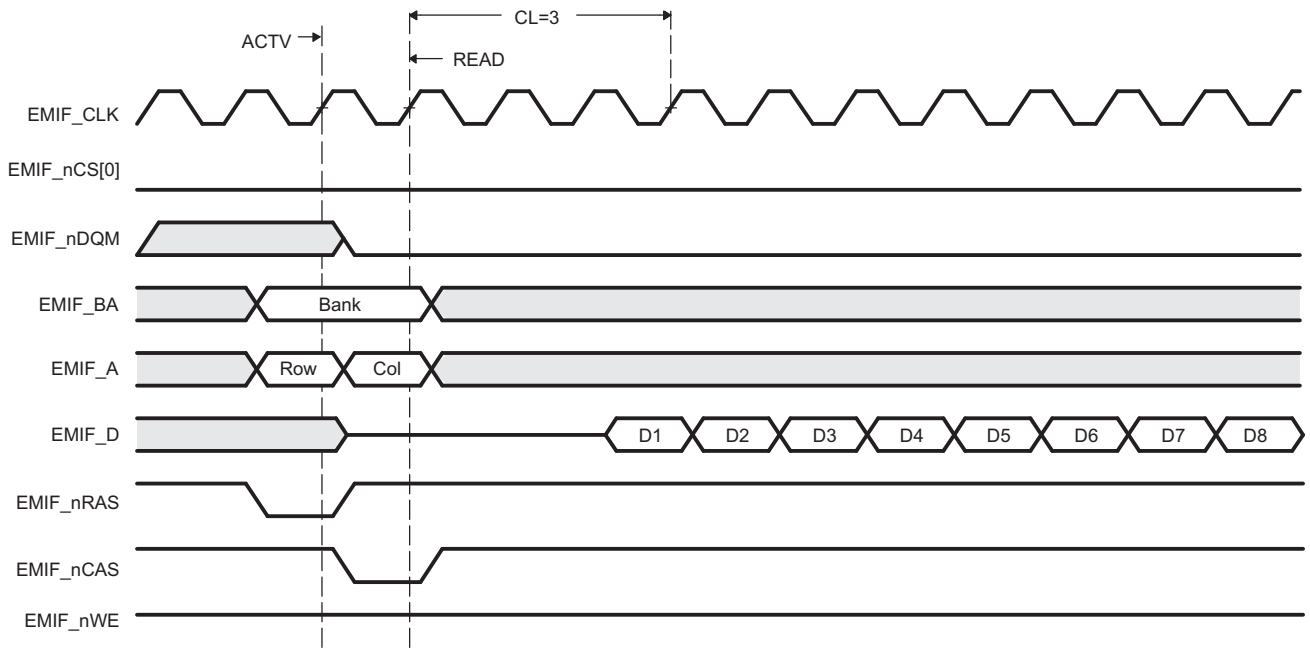
The PDWR bit in SDCR indicates whether the EMIF should perform refreshes in power-down state. If the PDWR bit is set, the EMIF exits the power-down state every time the Refresh Must level is set, performs AUTO REFRESH commands to the SDRAM, and returns back to the power-down state. This evenly distributes the refreshes to the SDRAM in power-down state. If the PDWR bit is not set, the EMIF does not perform any refreshes to the SDRAM. Therefore, the data integrity of the SDRAM is not assured upon power down exit if the PDWR bit is not set.

If the PD bit is cleared while in the power-down state, the EMIF will come out of the power-down state. The EMIF:

- Drives EMIF_CKE high.
- Enters its idle state.

Copyright © 2018, Texas Instruments Incorporated

21.2.5.9 SDRAM Read Operation



When the EMIF receives a read request to SDRAM from one of the requesters listed in Section 21.2.2, it performs one or more read access cycles. A read access cycle begins with the issuing of the ACTV command to select the desired bank and row of the SDRAM device. After the row has been opened, the EMIF proceeds to issue a READ command while specifying the desired bank and column address. EMIF_A[10] is held low during the READ command to avoid auto-precharging. The READ command signals the SDRAM device to start bursting data from the specified address while the EMIF issues NOP commands. Following a READ command, the CL field of the SDRAM configuration register (SDCR) defines how many delay cycles will be present before the read data appears on the data bus. This is referred to as the CAS latency.

Figure 21-5 shows the signal waveforms for a basic SDRAM read operation in which a burst of data is read from a single page. When the EMIF SDRAM interface is configured to 16 bit by setting the NM bit of the SDRAM configuration register (SDCR) to 1, a burst size of eight is used. Figure 21-5 shows a burst size of eight.

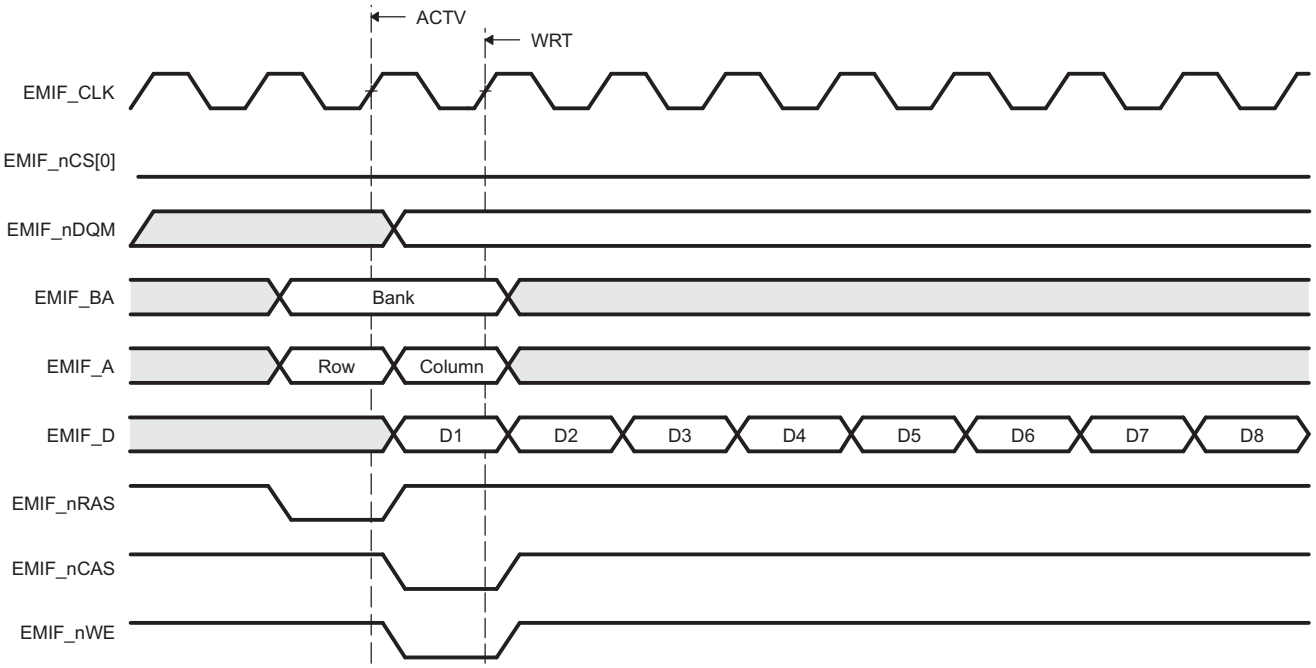
The EMIF will truncate a series of bursting data if the remaining addresses of the burst are not required to complete the request. The EMIF can truncate the burst in three ways:

- By issuing another READ to the same page in the same bank.
- By issuing a PRE command in order to prepare for accessing a different page of the same bank.
- By issuing a BT command in order to prepare for accessing a page in a different bank.

Figure 21-5. Timing Waveform for Basic SDRAM Read Operation

Several other pins are also active during a read access. The EMIF_nDQM[1:0] pins are driven low during the READ commands and are kept low during the NOP commands that correspond to the burst request. The state of the other EMIF pins during each command can be found in Table 21-5.

The EMIF schedules its commands based on the timing information that is provided to it in the SDRAM timing register (SDTIMR). The values for the timing parameters in this register should be chosen to satisfy the timing requirements listed in the SDRAM datasheet. The EMIF uses this timing information to avoid violating any timing constraints related to issuing commands. This is commonly accomplished by inserting NOP commands between various commands during an access. Refer to the register description of SDTIMR in Section 21.3.6 for more details on the various timing parameters.



Copyright © 2018, Texas Instruments Incorporated

21.2.5.10 SDRAM Write Operations

When the EMIF receives a write request to SDRAM from one of the requesters listed in Section 21.2.2, it performs one or more write-access cycles. A write-access cycle begins with the issuing of the ACTV command to select the desired bank and row of the SDRAM device. After the row has been opened, the EMIF proceeds to issue a WRT command while specifying the desired bank and column address. EMIF_A[10] is held low during the WRT command to avoid auto-precharging. The WRT command signals the SDRAM device to start writing a burst of data to the specified address while the EMIF issues NOP commands. The associated write data will be placed on the data bus in the cycle concurrent with the WRT command and with subsequent burst continuation NOP commands.

Figure 21-6 shows the signal waveforms for a basic SDRAM write operation in which a burst of data is read from a single page. When the EMIF SDRAM interface is configured to 16-bit by setting the NM bit of the SDRAM configuration register (SDCR) to 1, a burst size of eight is used. Figure 21-6 shows a burst size of eight.

Figure 21-6. Timing Waveform for Basic SDRAM Write Operation

The EMIF will truncate a series of bursting data if the remaining addresses of the burst are not part of the write request. The EMIF can truncate the burst in three ways:

- By issuing another WRT to the same page
- By issuing a PRE command in order to prepare for accessing a different page of the same bank
- By issuing a BT command in order to prepare for accessing a page in a different bank

Several other pins are also active during a write access. The EMIF_nDQM[1:0] pins are driven to select which bytes of the data word will be written to the SDRAM device. They are also used to mask out entire undesired data words during a burst access. The state of the other EMIF pins during each command can be found in Table 21-5.

The EMIF schedules its commands based on the timing information that is provided to it in the SDRAM timing register (SDTIMR). The values for the timing parameters in this register should be chosen to satisfy the timing requirements listed in the SDRAM datasheet. The EMIF uses this timing information to avoid violating any timing constraints related to issuing commands. This is commonly accomplished by inserting NOP commands during various cycles of an access. Refer to the register description of SDTIMR in Section 21.3.6 for more details on the various timing parameters.

Copyright © 2018, Texas Instruments Incorporated

21.2.5.11 Mapping from Logical Address to EMIF Pins

When the EMIF receives an SDRAM access request, it must convert the address of the access into the appropriate signals to send to the SDRAM device. The details of this address mapping are shown in Table 21-13 for 16-bit operation. Using the settings of the IBANK and PAGESIZE fields of the SDRAM configuration register (SDCR), the EMIF determines which bits of the logical address will be mapped to the SDRAM row, column, and bank addresses.

As the logical address is incremented by one halfword (16-bit operation), the column address is likewise incremented by one until a page boundary is reached. When the logical address increments across a page boundary, the EMIF moves into the same page in the next bank of the attached device by incrementing the bank address EMIF_BA and resetting the column address. The page in the previous bank is left open until it is necessary to close it. This method of traversal through the SDRAM banks helps maximize the number of open banks inside of the SDRAM and results in an efficient use of the device. There is no limitation on the number of banks that can be open at one time, but only one page within a bank can be open at a time.

The EMIF uses the EMIF_nDQM[1:0] pins during a WRT command to mask out selected bytes or entire words. The EMIF_nDQM[1:0] pins are always low during a READ command.

Table 21-13. Mapping from Logical Address to EMIF Pins for 16-bit SDRAM

IBANK	PAGESIZE	Logical Address													
		31:27	26	25	24	23	22	21:14	13	12	11	10	9	8:1	0
0	0	-						Row Address						Col Address	EMIF_nDQM[0]
1	0	-						Row Address					EMIF_BA[0]	Col Address	EMIF_nDQM[0]
2	0	-						Row Address				EMIF_BA[1:0]		Col Address	EMIF_nDQM[0]
0	1	-						Row Address					Column Address		EMIF_nDQM[0]
1	1	-						Row Address				EMIF_BA[0]	Column Address		EMIF_nDQM[0]
2	1	-						Row Address			EMIF_BA[1:0]		Column Address		EMIF_nDQM[0]
0	2	-						Row Address					Column Address		EMIF_nDQM[0]
1	2	-						Row Address			EMIF_BA[0]		Column Address		EMIF_nDQM[0]
2	2	-						Row Address		EMIF_BA[1:0]			Column Address		EMIF_nDQM[0]
0	3	-						Row Address					Column Address		EMIF_nDQM[0]
1	3	-						Row Address		EMIF_BA[0]			Column Address		EMIF_nDQM[0]
2	3	-						Row Address		EMIF_BA[1:0]			Column Address		EMIF_nDQM[0]

NOTE: The upper bit of the Row Address is used only when addressing 256-Mbit and 512-Mbit SDRAM memories.

Copyright © 2018, Texas Instruments Incorporated

21.2.6 Asynchronous Controller and Interface

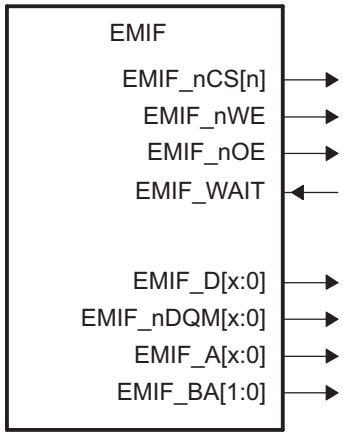
The EMIF easily interfaces to a variety of asynchronous devices including NOR Flash and SRAM. It can be operated in two major modes (see Table 21-14):

- Normal Mode
- Select Strobe Mode

Table 21-14. Normal Mode vs. Select Strobe Mode

Mode	Function of EMIF_nDQM pins	Operation of EMIF_nCS[4:2]
Normal Mode	Byte enables	Active during the entire asynchronous access cycle
Select Strobe Mode	Byte enables	Active only during the strobe period of an access cycle

The first mode of operation is Normal Mode, in which the EMIF_nDQM pins of the EMIF function as byte enables. In this mode, the EMIF_nCS[4:2] pins behaves as typical chip select signals, remaining active for the duration of the asynchronous access. See Section 21.2.6.1 for an example interface with multiple 8-bit devices.



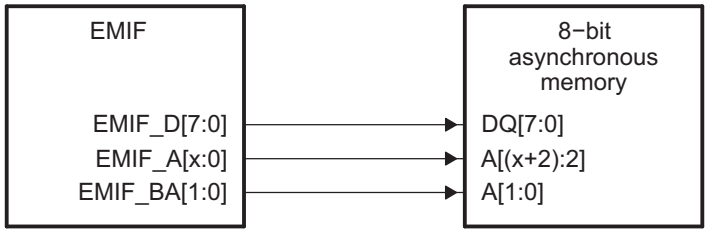
The second mode of operation is Select Strobe Mode, in which the EMIF_nCS[4:2] pins act as a strobe, active only during the strobe period of an access. In this mode, the EMIF_nDQM pins of the EMIF function as standard byte enables for reads and writes. A summary of the differences between the two modes of operation are shown in Table 21-14. Refer to Section 21.2.6.4 for the details of asynchronous operations in Normal Mode, and to Section 21.2.6.5 for the details of asynchronous operations in Select Strobe Mode. The EMIF hardware defaults to Normal Mode, but can be manually switched to Select Strobe Mode by setting the SS bit in the asynchronous *m* (m = 1, 2, 3, or 4) configuration register (CE*n*CFG) (*n* = 2, 3, or 4). Throughout the chapter, *m* can hold the values 1, 2, 3 or 4; and *n* can hold the values 2, 3, or 4.

The EMIF also provides configurable cycle timing parameters and an Extended Wait Mode that allows the connected device to extend the strobe period of an access cycle. The following sections describe the features related to interfacing with external asynchronous devices.

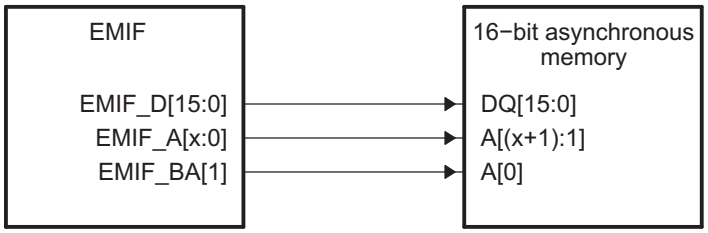
21.2.6.1 Interfacing to Asynchronous Memory

Figure 21-7 shows the EMIF's external pins used in interfacing with an asynchronous device. In EMIF_nCS[n], n = 2, 3, or 4.

Figure 21-7. EMIF Asynchronous Interface



Copyright © 2018, Texas Instruments Incorporated



Of special note is the connection between the EMIF and the external device's address bus. The EMIF address pin EMIF_A[0] always provides the least significant bit of a 32-bit word address. Therefore, when interfacing to a 16-bit or 8-bit asynchronous device, the EMIF_BA[1] and EMIF_BA[0] pins provide the least-significant bits of the halfword or byte address, respectively. Additionally, when the EMIF interfaces to a 16-bit asynchronous device, the EMIF_BA[0] pin can serve as the upper address line EMIF_A[22]. Figure 21-8 and Figure 21-9 show the mapping between the EMIF and the connected device's data and address pins for various programmed data bus widths. The data bus width may be configured in the asynchronous *n* configuration register (CE*n*CFG).

Figure 21-9 shows a common interface between the EMIF and external asynchronous memory. Figure 21-9 shows an interface between the EMIF and an external memory with byte enables. The EMIF should be operated in either Normal Mode or Select Strobe Mode when using this interface, so that the EMIF_nDQM signals operate as byte enables.

Figure 21-8. EMIF to 8-bit/16-bit Memory Interface

21.2.6.2 Accessing Larger Asynchronous Memories

The device has 22 dedicated EMIF address lines. If a device such as a large asynchronous flash needs to be attached to the EMIF, then GPIO pins may be used to control the flash device's upper address lines.

21.2.6.3 Configuring the EMIF for Asynchronous Accesses

The operation of the EMIF's asynchronous interface can be configured by programming the appropriate register fields. The reset value and bit position for each register field can be found in Section 21.3. The following tables list the register fields that can be programmed and describe the purpose of each field. These registers can be programmed prior to accessing the external memory, and the transfer following a write to these registers will use the new configuration.

Table 21-15. Description of the Asynchronous *m* Configuration Register (CE*n*CFG)

Parameter	Description
SS	**Select Strobe mode.** This bit selects the EMIF's mode of operation in the following way: • SS = 0 selects Normal Mode – EMIF_nDQM pins function as byte enables – EMIF_nCS[4:2] active for duration of access • SS = 1 selects Select Strobe Mode – EMIF_nDQM pins function as byte enables – EMIF_nCS[4:2] acts as a strobe.
EW	**Extended Wait Mode enable.** • EW = 0 disables Extended Wait Mode • EW = 1 enables Extended Wait Mode When set to 1, the EMIF enables its Extended Wait Mode in which the strobe width of an access cycle can be extended in response to the assertion of the EMIF_nWAIT pin. The WP*n* bit in the asynchronous wait cycle configuration register (AWCC) controls to polarity of EMIF_nWAIT pin. See Section 21.2.6.6 for more details on this mode of operation.
W_SETUP/R_SETUP	**Read/Write setup widths.** These fields define the number of EMIF clock cycles of setup time for the address pins (EMIF_A and EMIF_BA), byte enables (EMIF_nDQM), and asynchronous chip enable (EMIF_nCS[4:2]) before the read strobe pin (EMIF_nOE) or write strobe pin (EMIF_nWE) falls, minus one cycle. For writes, the W_SETUP field also defines the setup time for the data pins (EMIF_D). Refer to the datasheet of the external asynchronous device to determine the appropriate setting for this field.
W_STROBE/R_STROBE	**Read/Write strobe widths.** These fields define the number of EMIF clock cycles between the falling and rising of the read strobe pin (EMIF_nOE) or write strobe pin (EMIF_nWE), minus one cycle. If Extended Wait Mode is enabled by setting the EW field in the asynchronous *n* configuration register (CE*n*CFG), these fields must be set to a value greater than zero. Refer to the datasheet of the external asynchronous device to determine the appropriate setting for this field.
W_HOLD/R_HOLD	**Read/Write hold widths.** These fields define the number of EMIF clock cycles of hold time for the address pins (EMIF_A and EMIF_BA), byte enables (EMIF_nDQM), and asynchronous chip enable (EMIF_nCS[4:2]) after the read strobe pin (EMIF_nOE) or write strobe pin (EMIF_nWE) rises, minus one cycle. For writes, the W_HOLD field also defines the hold time for the data pins (EMIF_D). Refer to the datasheet of the external asynchronous device to determine the appropriate setting for this field.
TA	**Minimum turnaround time.** This field defines the minimum number of EMIF clock cycles between asynchronous reads and writes, minus one cycle. The purpose of this feature is to avoid contention on the bus. The value written to this field also determines the number of cycles that will be inserted between asynchronous accesses and SDRAM accesses. Refer to the datasheet of the external asynchronous device to determine the appropriate setting for this field.

Copyright © 2018, Texas Instruments Incorporated

Table 21-15. Description of the Asynchronous *m* Configuration Register (CE*n*CFG) (continued)

Parameter	Description
ASIZE	**Asynchronous Device Bus Width.** This field determines the data bus width of the asynchronous interface in the following way: • ASIZE = 0 selects an 8-bit bus • ASIZE = 1 selects a 16-bit bus The configuration of ASIZE determines the function of the EMIF_A and EMIF_BA pins as described in Section 21.2.6.1. This field also determines the number of external accesses required to fulfill a request generated by one of the sources mentioned in Section 21.2.2. For example, a request for a 32-bit word would require four external access when ASIZE = 0. Refer to the datasheet of the external asynchronous device to determine the appropriate setting for this field.

Table 21-16. Description of the Asynchronous Wait Cycle Configuration Register (AWCC)

Parameter	Description
WP*n*	**EM_WAIT Polarity.** • WP*n* = 0 selects active-low polarity • WP*n* = 1 selects active-high polarity When set to 1, the EMIF will wait if the EMIF_nWAIT pin is high. When cleared to 0, the EMIF will wait if the EMIF_nWAIT pin is low. The EMIF must have the Extended Wait Mode enabled for the EMIF_nWAIT pin to affect the width of the strobe period.
MAX_EXT_WAIT	**Maximum Extended Wait Cycles.** This field configures the number of EMIF clock cycles the EMIF will wait for the EMIF_nWAIT pin to be deactivated during the strobe period of an access cycle. The maximum number of EMIF clock cycles it will wait is determined by the following formula: Maximum Extended Wait Cycles = (MAX_EXT_WAIT + 1) × 16 If the EMIF_nWAIT pin is not deactivated within the time specified by this field, the EMIF resumes the access cycle, registering whatever data is on the bus and proceeding to the hold period of the access cycle. This situation is referred to as an Asynchronous Timeout. An Asynchronous Timeout generates an interrupt, if it has been enabled in the EMIF interrupt mask set register (INTMSKSET). Refer to Section 21.2.9.1 for more information about the EMIF interrupts.

Table 21-17. Description of the EMIF Interrupt Mask Set Register (INTMSKSET)

Parameter	Description
WR_MASK_SET	**Wait Rise Mask Set.** Writing a 1 enables an interrupt to be generated when a rising edge on EMIF_nWAIT occurs
AT_MASK_SET	**Asynchronous Timeout Mask Set.** Writing a 1 to this bit enables an interrupt to be generated when an Asynchronous Timeout occurs.

Table 21-18. Description of the EMIF Interrupt Mast Clear Register (INTMSKCLR)

Parameter	Description
WR_MASK_CLR	**Wait Rise Mask Clear.** Writing a 1 to this bit disables the interrupt, clearing the WR_MASK_SET bit in the EMIF interrupt mask set register (INTMSKSET).
AT_MASK_CLR	**Asynchronous Timeout Mask Clear.** Writing a 1 to this bit prevents an interrupt from being generated when an Asynchronous Timeout occurs.

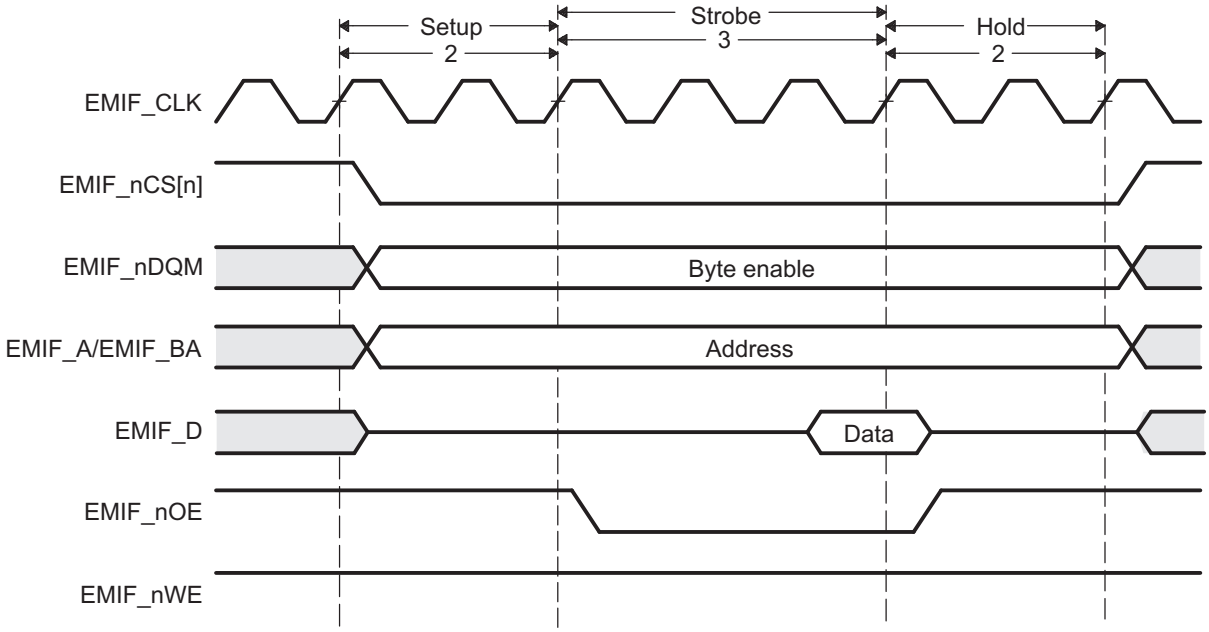
21.2.6.4 Read and Write Operations in Normal Mode

Normal Mode is the asynchronous interface's default mode of operation. It is selected when the SS bit in the asynchronous *n* configuration register (CE*n*CFG) is cleared to 0. In this mode, the EMIF_nDQM pins operate as byte enables. Section 21.2.6.4.1 and Section 21.2.6.4.2 explain the details of read and write operations while in Normal Mode.

21.2.6.4.1 Asynchronous Read Operations (Normal Mode)

NOTE: During an entire asynchronous read operation, the EMIF_nWE pin is driven high.



An asynchronous read is performed when any of the requesters mentioned in Section 21.2.2 request a read from the attached asynchronous memory. After the request is received, a read operation is initiated once it becomes the EMIF's highest priority task, according to the priority scheme detailed in Section 21.2.13. In the event that the read request cannot be serviced by a single access cycle to the external device, multiple access cycles will be performed by the EMIF until the entire request is fulfilled. The details of an asynchronous read operation in Normal Mode are described in Table 21-19. Also, Figure 21-10 shows an example timing diagram of a basic read operation.

Table 21-19. Asynchronous Read Operation in Normal Mode

Time Interval	Pin Activity in Normal Mode
Turn-around period	Once the read operation becomes the highest priority task for the EMIF, the EMIF waits for the programmed number of turn-around cycles before proceeding to the setup period of the operation. The number of wait cycles is taken directly from the TA field of the asynchronous *n* configuration register (CE*n*CFG). There are two exceptions to this rule: • If the current read operation was directly proceeded by another read operation, no turnaround cycles are inserted. • If the current read operation was directly proceeded by a write operation and the TA field has been cleared to 0, one turn-around cycle will be inserted. After the EMIF has waited for the turnaround cycles to complete, it again checks to make sure that the read operation is still its highest priority task. If so, the EMIF proceeds to the setup period of the operation. If it is no longer the highest priority task, the EMIF terminates the operation.
Start of the setup period	The following actions occur at the start of the setup period: • The setup, strobe, and hold values are set according to the R_SETUP, R_STROBE, and R_HOLD values in CE*n*CFG. • The address pins EMIF_A and EMIF_BA become valid and carry the values described in Section 21.2.6.1. • EMIF_nCS[4:2] falls to enable the external device (if not already low from a previous operation)
Strobe period	The following actions occur during the strobe period of a read operation: 1. EMIF_nOE falls at the start of the strobe period 2. On the rising edge of the clock which is concurrent with the end of the strobe period: • EMIF_nOE rises • The data on the EMIF_D bus is sampled by the EMIF. In Figure 21-10, EMIF_nWAIT is inactive. If EMIF_nWAIT is instead activated, the strobe period can be extended by the external device to give it more time to provide the data. Section 21.2.6.6 contains more details on using the EMIF_nWAIT pin.
End of the hold period	At the end of the hold period: • The address pins EMIF_A and EMIF_BA become invalid • EMIF_nCS[4:2] rises (if no more operations are required to complete the current request) EMIF may be required to issue additional read operations to a device with a small data bus width in order to complete an entire word access. In this case, the EMIF immediately re-enters the setup period to begin another operation without incurring the turn-round cycle delay. The setup, strobe, and hold values are not updated in this case. If the entire word access has been completed, the EMIF returns to its previous state unless another asynchronous request has been submitted and is currently the highest priority task. If this is the case, the EMIF instead enters directly into the turnaround period for the pending read or write operation.

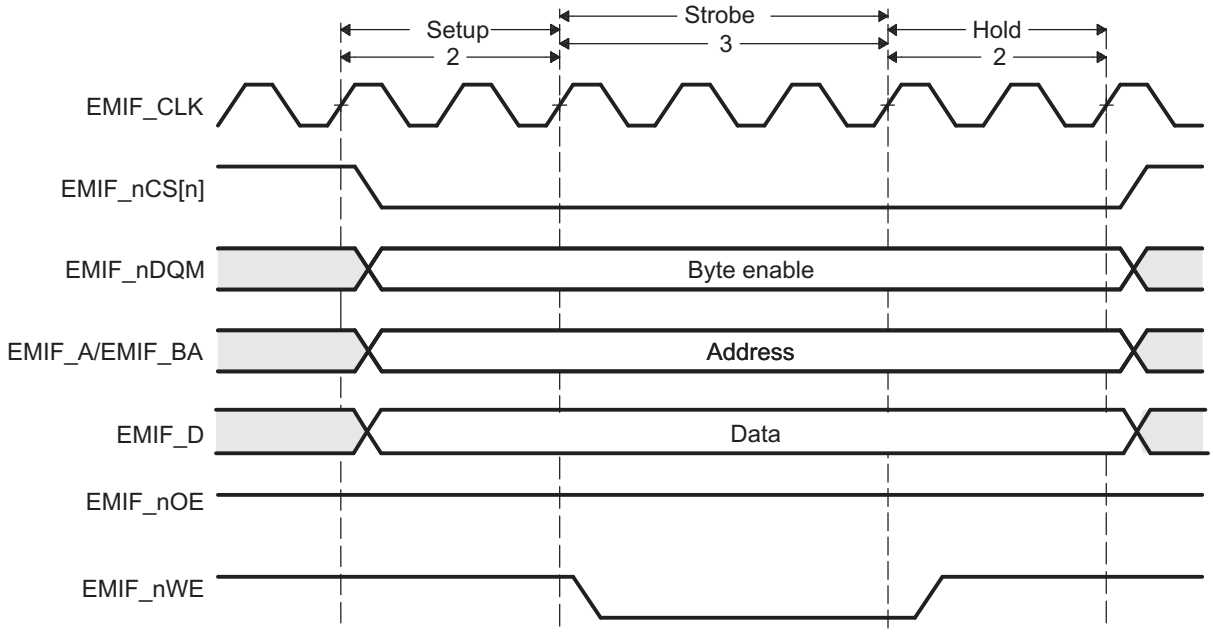
21.2.6.4.2 Asynchronous Write Operations (Normal Mode)

NOTE: During an entire asynchronous write operation, the EMIF_nOE pin is driven high.



An asynchronous write is performed when any of the requesters mentioned in Section 21.2.2 request a write to memory in the asynchronous bank of the EMIF. After the request is received, a write operation is initiated once it becomes the EMIF's highest priority task, according to the priority scheme detailed in Section 21.2.13. In the event that the write request cannot be serviced by a single access cycle to the external device, multiple access cycles will be performed by the EMIF until the entire request is fulfilled. The details of an asynchronous write operation in Normal Mode are described in Table 21-20. Also, Figure 21-11 shows an example timing diagram of a basic write operation.

Table 21-20. Asynchronous Write Operation in Normal Mode

Time Interval	Pin Activity in Normal Mode
Turnaround period	Once the write operation becomes the highest priority task for the EMIF, the EMIF waits for the programmed number of turn-around cycles before proceeding to the setup period of the operation. The number of wait cycles is taken directly from the TA field of the asynchronous *n* configuration register (CE*n*CFG). There are two exceptions to this rule: • If the current write operation was directly proceeded by another write operation, no turn-around cycles are inserted. • If the current write operation was directly proceeded by a read operation and the TA field has been cleared to 0, one turnaround cycle will be inserted. After the EMIF has waited for the turn-around cycles to complete, it again checks to make sure that the write operation is still its highest priority task. If so, the EMIF proceeds to the setup period of the operation. If it is no longer the highest priority task, the EMIF terminates the operation.
Start of the setup period	The following actions occur at the start of the setup period: • The setup, strobe, and hold values are set according to the W_SETUP, W_STROBE, and W_HOLD values in CE*n*CFG. • The address pins EMIF_A and EMIF_BA and the data pins EMIF_D become valid. The EMIF_A and EMIF_BA pins carry the values described in Section 21.2.6.1. • EMIF_nCS[4:2] falls to enable the external device (if not already low from a previous operation).
Strobe period	The following actions occur at the start of the strobe period of a write operation: 1. EMIF_nWE falls 2. The EMIF_nDQM pins become valid as byte enables. The following actions occur on the rising edge of the clock which is concurrent with the end of the strobe period: 1. EMIF_nWE rises 2. The EMIF_nDQM pins deactivate In Figure 21-11, EMIF_nWAIT is inactive. If EMIF_nWAIT is instead activated, the strobe period can be extended by the external device to give it more time to accept the data. Section 21.2.6.6 contains more details on using the EMIF_nWAIT pin.
End of the hold period	At the end of the hold period: • The address pins EMIF_A and EMIF_BA become invalid • The data pins become invalid • EMIF_nCS[n] (n = 2, 3, or 4) rises (if no more operations are required to complete the current request) The EMIF may be required to issue additional write operations to a device with a small data bus width in order to complete an entire word access. In this case, the EMIF immediately re-enters the setup period to begin another operation without incurring the turnaround cycle delay. The setup, strobe, and hold values are not updated in this case. If the entire word access has been completed, the EMIF returns to its previous state unless another asynchronous request has been submitted and is currently the highest priority task. If this is the case, the EMIF instead enters directly into the turnaround period for the pending read or write operation.

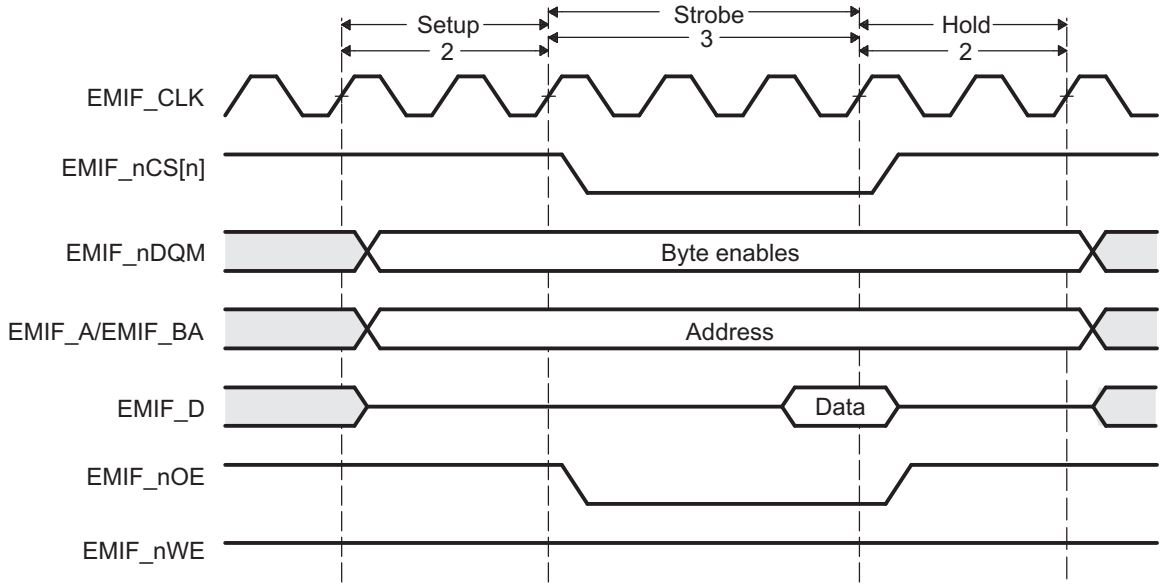
21.2.6.5 Read and Write Operation in Select Strobe Mode

Select Strobe Mode is the EMIF's second mode of operation. It is selected when the SS bit of the asynchronous *n* configuration register (CE*n*CFG) is set to 1. In this mode, the EMIF_nDQM pins operate as byte enables and the EMIF_nCS[n] (n = 2, 3, or 4) pin is only active during the strobe period of an access cycle. Section 21.2.6.4.1 and Section 21.2.6.4.2 explain the details of read and write operations while in Select Strobe Mode.

21.2.6.5.1 Asynchronous Read Operations (Select Strobe Mode)

NOTE: During the entirety of an asynchronous read operation, the EMIF_nWE pin is driven high.



An asynchronous read is performed when any of the requesters mentioned in Section 21.2.2 request a read from the attached asynchronous memory. After the request is received, a read operation is initiated once it becomes the EMIF's highest priority task, according to the priority scheme detailed in Section 21.2.13. In the event that the read request cannot be serviced by a single access cycle to the external device, multiple access cycles will be performed by the EMIF until the entire request is fulfilled. The details of an asynchronous read operation in Select Strobe Mode are described in Table 21-21. Also, Figure 21-12 shows an example timing diagram of a basic read operation.

Table 21-21. Asynchronous Read Operation in Select Strobe Mode

Time Interval	Pin Activity in Select Strobe Mode
Turnaround period	Once the read operation becomes the highest priority task for the EMIF, the EMIF waits for the programmed number of turn-around cycles before proceeding to the setup period of the operation. The number of wait cycles is taken directly from the TA field of the asynchronous *n* configuration register (CE*n*CFG). There are two exceptions to this rule: • If the current read operation was directly proceeded by another read operation, no turn-around cycles are inserted. • If the current read operation was directly proceeded by a write operation and the TA field has been cleared to 0, one turn-around cycle will be inserted. After the EMIF has waited for the turn-around cycles to complete, it again checks to make sure that the read operation is still its highest priority task. If so, the EMIF proceeds to the setup period of the operation. If it is no longer the highest priority task, the EMIF terminates the operation.
Start of the setup period	The following actions occur at the start of the setup period: • The setup, strobe, and hold values are set according to the R_SETUP, R_STROBE, and R_HOLD values in CE*n*CFG. • The address pins EMIF_A and EMIF_BA become valid and carry the values described in Section 21.2.6.1. • The EMIF_nDQM pins become valid as byte enables.
Strobe period	The following actions occur during the strobe period of a read operation: 1. EMIF_nCS[n] (n = 2, 3, or 4) and EMIF_nOE fall at the start of the strobe period 2. On the rising edge of the clock which is concurrent with the end of the strobe period: • EMIF_nCS[n] (n = 2, 3, or 4) and EMIF_nOE rise • The data on the EMIF_D bus is sampled by the EMIF. In Figure 21-12, EMIF_nWAIT is inactive. If EMIF_nWAIT is instead activated, the strobe period can be extended by the external device to give it more time to provide the data. Section 21.2.6.6 contains more details on using the EMIF_nWAIT pin.
End of the hold period	At the end of the hold period: • The address pins EMIF_A and EMIF_BA become invalid • The EMIF_nDQM pins become invalid The EMIF may be required to issue additional read operations to a device with a small data bus width in order to complete an entire word access. In this case, the EMIF immediately re-enters the setup period to begin another operation without incurring the turnaround cycle delay. The setup, strobe, and hold values are not updated in this case. If the entire word access has been completed, the EMIF returns to its previous state unless another asynchronous request has been submitted and is currently the highest priority task. If this is the case, the EMIF instead enters directly into the turnaround period for the pending read or write operation.

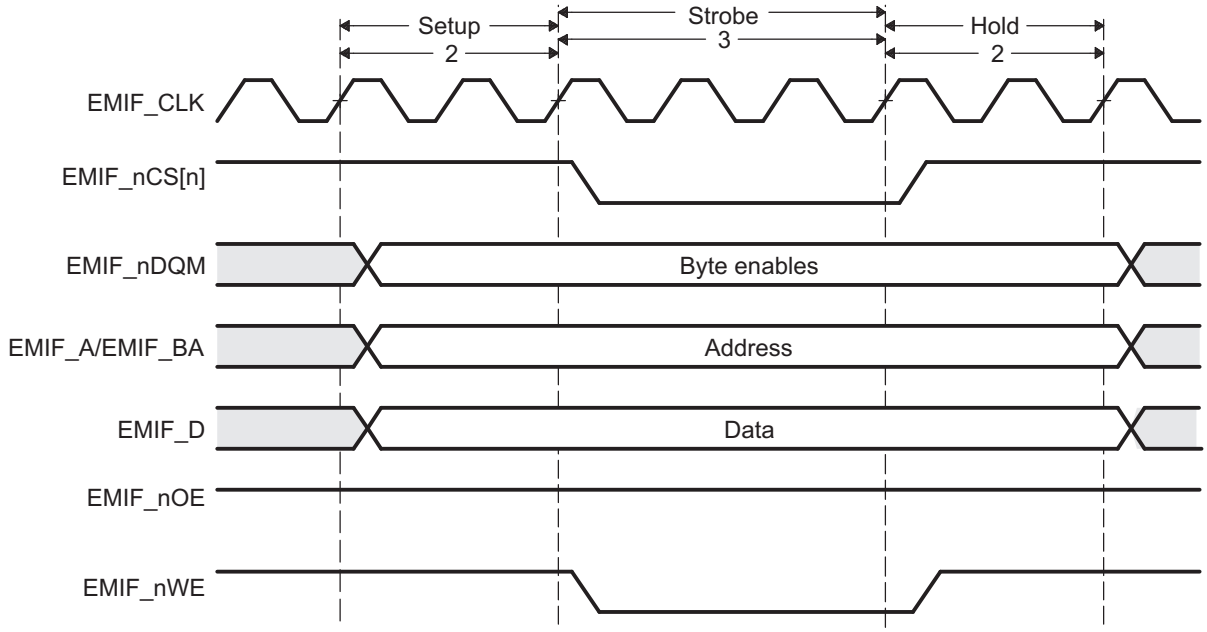
21.2.6.5.2 Asynchronous Write Operations (Select Strobe Mode)

NOTE: During the entirety of an asynchronous write operation, the EMIF_nOE pin is driven high.



An asynchronous write is performed when any of the requesters mentioned in Section 21.2.2 request a write to memory in the asynchronous bank of the EMIF. After the request is received, a write operation is initiated once it becomes the EMIF's highest priority task, according to the priority scheme detailed in Section 21.2.13. In the event that the write request cannot be serviced by a single access cycle to the external device, multiple access cycles will be performed by the EMIF until the entire request is fulfilled. The details of an asynchronous write operation in Select Strobe Mode are described in Table 21-22. Also, Figure 21-13 shows an example timing diagram of a basic write operation.

Table 21-22. Asynchronous Write Operation in Select Strobe Mode

Time Interval	Pin Activity in Select Strobe Mode
Turnaround period	Once the write operation becomes the highest priority task for the EMIF, the EMIF waits for the programmed number of turnaround cycles before proceeding to the setup period of the operation. The number of wait cycles is taken directly from the TA field of the asynchronous *n* configuration register (CE*n*CFG). There are two exceptions to this rule: • If the current write operation was directly proceeded by another write operation, no turn-around cycles are inserted. • If the current write operation was directly proceeded by a read operation and the TA field has been cleared to 0, one turnaround cycle will be inserted. After the EMIF has waited for the turnaround cycles to complete, it again checks to make sure that the write operation is still its highest priority task. If so, the EMIF proceeds to the setup period of the operation. If it is no longer the highest priority task, the EMIF terminates the operation.
Start of the setup period	The following actions occur at the start of the setup period: • The setup, strobe, and hold values are set according to the W_SETUP, W_STROBE, and W_HOLD values in CE*n*CFG. • The address pins EMIF_A and EMIF_BA and the data pins EMIF_D become valid. The EMIF_A and EMIF_BA pins carry the values described in Section 21.2.6.1. • The EMIF_nDQM pins become active as byte enables.
Strobe period	The following actions occur at the start of the strobe period of a write operation: • EMIF_nCS[n] (n = 2, 3, or 4) and EMIF_nWE fall The following actions occur on the rising edge of the clock which is concurrent with the end of the strobe period: • EMIF_nCS[n] (n = 2, 3, or 4) and EMIF_nWE rise In Figure 21-13, EMIF_nWAIT is inactive. If EMIF_nWAIT is instead activated, the strobe period can be extended by the external device to give it more time to accept the data. Section 21.2.6.6 contains more details on using the EMIF_nWAIT pin.
End of the hold period	At the end of the hold period: • The address pins EMIF_A and EMIF_BA become invalid • The data pins become invalid • The EMIF_nDQM pins become invalid The EMIF may be required to issue additional write operations to a device with a small data bus width in order to complete an entire word access. In this case, the EMIF immediately re-enters the setup period to begin another operation without incurring the turnaround cycle delay. The setup, strobe, and hold values are not updated in this case. If the entire word access has been completed, the EMIF returns to its previous state unless another asynchronous request has been submitted and is currently the highest priority task. If this is the case, the EMIF instead enters directly into the turn-around period for the pending read or write operation.

Figure 21-13. Timing Waveform of an Asynchronous Write Cycle in Select Strobe Mode

21.2.6.6 Extended Wait Mode and the EMIF_nWAIT Pin

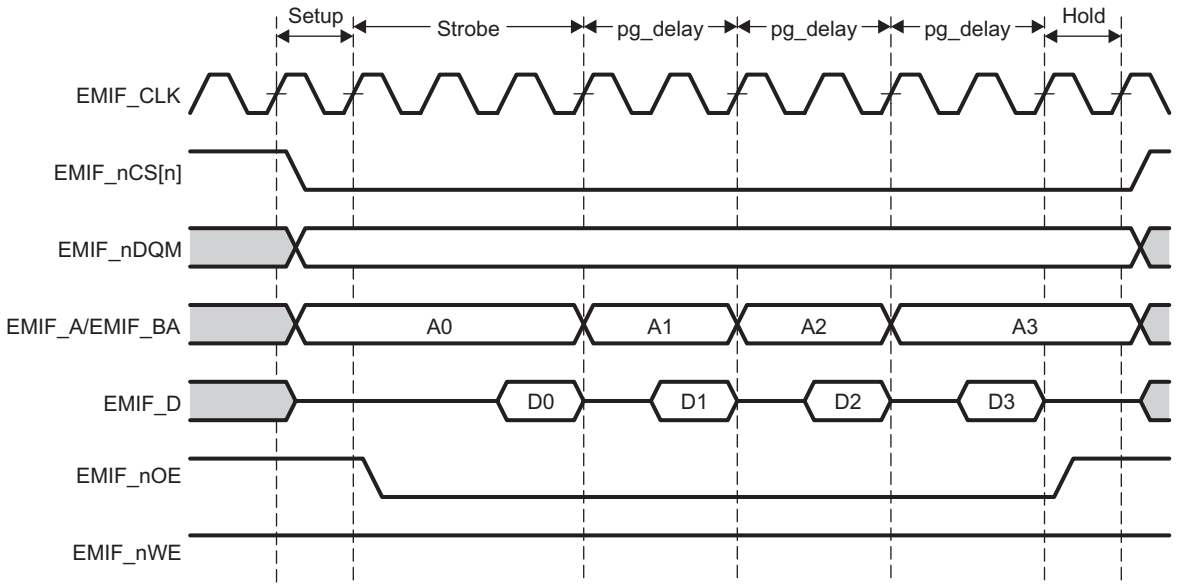
The EMIF supports the Extend Wait Mode. This is a mode in which the external asynchronous device may assert control over the length of the strobe period. The Extended Wait Mode can be entered by setting the EW bit in the asynchronous *n* configuration register (CE*n*CFG) (*n* = 2, 3, or 4). When this bit is set, the EMIF monitors the EMIF_nWAIT pin to determine if the attached device wishes to extend the strobe period of the current access cycle beyond the programmed number of clock cycles.

When the EMIF detects that the EMIF_nWAIT pin has been asserted, it will begin inserting extra strobe cycles into the operation until the EMIF_nWAIT pin is deactivated by the external device. The EMIF will then return to the last cycle of the programmed strobe period and the operation will proceed as usual from this point. Please refer to the device data manual for details on the timing requirements of the EMIF_nWAIT signal.

The EMIF_nWAIT pin cannot be used to extend the strobe period indefinitely. The programmable MAX_EXT_WAIT field in the asynchronous wait cycle configuration register (AWCC) determines the maximum number of EMIF_CLK cycles the strobe period may be extended beyond the programmed length. When the counter expires, the EMIF proceeds to the hold period of the operation regardless of the state of the EMIF_nWAIT pin. The EMIF can also generate an interrupt upon expiration of this counter. See Section 21.2.9.1 for details on enabling this interrupt.

For the EMIF to function properly in the Extended Wait mode, the WP*n* bit of AWCC must be programmed to match the polarity of the EMIF_nWAIT pin. In its reset state of 1, the EMIF will insert wait cycles when the EMIF_nWAIT pin is sampled high. When set to 0, the EMIF will insert wait cycles only when EMIF_nWAIT is sampled low. This programmability allows for a glueless connection to larger variety of asynchronous devices.

Finally, a restriction is placed on the strobe period timing parameters when operating in Extended Wait mode. Specifically, the sum of the W_SETUP and W_STROBE fields must be greater than 4, and the sum of the R_SETUP and R_STROBE fields must be greater than 4 for the EMIF to recognize the EMIF_nWAIT pin has been asserted. The W_SETUP, W_STROBE, R_SETUP, and R_STROBE fields are in CE*n*CFG.



Copyright © 2018, Texas Instruments Incorporated

21.2.6.7 NOR Flash Page Mode

EMIF supports Page mode reads for NOR Flash on its asynchronous memory chip selects. This mode can be enabled by writing a 1 to the CS*n*_PG_MD_EN (*n* = 2, 3, or 4) field in the Page Mode Control register for the chip select in consideration. Whenever Page Mode for reads is enabled for a particular chip select, the page size for the device connected must also be programmed in the CS*n*_PG_SIZE field of the Page Mode Control register. The address change to valid read data available timing must be programmed in the CS*n*_PG_DEL field of the Page Control register. All other asynchronous memory timings must be programmed in the asynchronous configuration register (CE*n*CFG). See Figure 21-14 for read in asynchronous page mode.

NOTE: The Extended Wait mode and the Select Strobe mode must be disabled when using the asynchronous interface in Page mode.

Figure 21-14. Asynchronous Read in Page Mode

21.2.7 Data Bus Parking

The EMIF always drives the data bus to the previous write data value when it is idle. This feature is called data bus parking. Only when the EMIF issues a read command to the external memory does it stop driving the data bus. After the EMIF latches the last read data, it immediately parks the data bus again.

The one exception to this behavior occurs after performing an asynchronous read operation while the EMIF is in the self-refresh state. In this situation, the read operation is not followed by the EMIF parking the data bus. Instead, the EMIF tri-states the data bus. Therefore, it is not recommended to perform asynchronous read operations while the EMIF is in the self-refresh state, in order to prevent floating inputs on the data bus. External pull-ups, such as 10kΩ resistors, should be placed on the 16 EMIF data bus pins (which do not have internal pull-ups) if it is required to perform reads in this situation. The precise resistor value should be chosen so that the worst case combined off-state leakage currents do not cause the voltage levels on the associated pins to drop below the high-level input voltage requirement.

For information about the self-refresh state, see Section 21.2.5.7.

Copyright © 2018, Texas Instruments Incorporated

21.2.8 Reset and Initialization Considerations

The EMIF memory controller has two active-low reset signals, CHIP_RST_n and MOD_G_RST_n. Both these reset signals are driven by the device system reset signal. This device does not offer the flexibility to reset just the EMIF state machine without also resetting the EMIF controller's memory-mapped registers. As soon as the device system reset is released (driven High), the EMIF memory controller immediately begins its initialization sequence. Command and data stored in the EMIF memory controller FIFOs are lost. Refer the Architecture chapter of the tecnical reference manual (TRM) for more information on conditions that can cause a device system reset to be asserted.

When system reset is released, the EMIF automatically begins running the SDRAM initialization sequence described in Section 21.2.5.4. Even though the initialization procedure is automatic, a special procedure, found in Section 21.2.5.5 must still be followed.

21.2.9 Interrupt Support

The EMIF supports a single interrupt to the CPU. Section 21.2.9.1 details the generation and internal masking of EMIF interrupts.

21.2.9.1 Interrupt Events

There are three conditions that may cause the EMIF to generate an interrupt to the CPU. These conditions are:

- A rising edge on the EMIF_nWAIT signal (wait rise interrupt)
- An asynchronous time out
- Usage of unsupported addressing mode (line trap interrupt)

The wait rise interrupt occurs when a rising edge is detected on EMIF_nWAIT signal. This interrupt generation is not affected by the WP*n* bit in the asynchronous wait cycle configuration register (AWCC). The asynchronous time out interrupt condition occurs when the attached asynchronous device fails to deassert the EMIF_nWAIT pin within the number of cycles defined by the MAX_EXT_WAIT bit in AWCC (this happens only in extended wait mode). EMIF supports only linear incrementing and cache line wrap addressing modes . If an access request for an unsupported addressing mode is received, the EMIF will set the LT bit in the EMIF interrupt raw register (INTRAW) and treat the request as a linear incrementing request.

Only when the interrupt is enabled by setting the appropriate bit (WR_MASK_SET/AT_MASK_SET/LT_MASK_SET) in the EMIF interrupt mask set register (INTMSKSET) to 1, will the interrupt be sent to the CPU. Once enabled, the interrupt may be disabled by writing a 1 to the corresponding bit in the EMIF interrupt mask clear register (INTMSKCLR). The bit fields in both the INTMSKSET and INTMSKCLR may be used to indicate whether the interrupt is enabled. When the interrupt is enabled, the corresponding bit field in both the INTMSKSET and INTMSKCLR will have a value of 1; when the interrupt is disabled, the corresponding bit field will have a value of 0.

The EMIF interrupt raw register (INTRAW) and the EMIF interrupt mask register (INTMSK) indicate the status of each interrupt. The appropriate bit (WR/AT/LT) in INTRAW is set when the interrupt condition occurs, whether or not the interrupt has been enabled. However, the appropriate bit (WR_MASKED/AT_MASKED/LT_MASKED) in INTMSK is set only when the interrupt condition occurs and the interrupt is enabled. Writing a 1 to the bit in INTRAW clears the INTRAW bit as well as the corresponding bit in INTMSK. Table 21-23 contains a brief summary of the interrupt status and control bit fields. See Section 21.3 for complete details on the register fields.

Copyright © 2018, Texas Instruments Incorporated

Table 21-23. Interrupt Monitor and Control Bit Fields

Register Name	Bit Name	Description
EMIF interrupt raw register (INTRAW)	WR	This bit is set when an rising edge on the EMIF_nWAIT signal occurs. Writing a 1 clears the WR bit as well as the WR_MASKED bit in INTMSK.
	AT	This bit is set when an asynchronous timeout occurs. Writing a 1 clears the AT bit as well as the AT_MASKED bit in INTMSK.
	LT	This bit is set when an unsupported addressing mode is used. Writing a 1 clears LT bit as well as the LT_MASKED bit in INTMSK.
EMIF interrupt mask register (INTMSK)	WR_MASKED	This bit is set only when a rising edge on the EMIF_nWAIT signal occurs and the interrupt has been enabled by writing a 1 to the WR_MASK_SET bit in INTMSKSET.
	AT_MASKED	This bit is set only when an asynchronous timeout occurs and the interrupt has been enabled by writing a 1 to the AT_MASK_SET bit in INTMSKSET.
	LT_MASKED	This bit is set only when line trap interrupt occurs and the interrupt has been enabled by writing a 1 to the LT_MASK_SET bit in INTMSKSET.
EMIF interrupt mask set register (INTMSKSET)	WR_MASK_SET	Writing a 1 to this bit enables the wait rise interrupt.
	AT_MASK_SET	Writing a 1 to this bit enables the asynchronous timeout interrupt.
	LT_MASK_SET	Writing a 1 to this bit enables the line trap interrupt.
EMIF interrupt mask clear register (INTMSKCLR)	WR_MASK_CLR	Writing a 1 to this bit disables the wait rise interrupt.
	AT_MASK_CLR	Writing a 1 to this bit disables the asynchronous timeout interrupt.
	LT_MASK_CLR	Writing a 1 to this bit disables the line trap interrupt.

21.2.10 DMA Event Support

EMIF memory controller is a DMA slave peripheral and therefore does not generate DMA events. Data read and write requests may be made directly, by masters and the DMA.

21.2.11 EMIF Signal Multiplexing

For details on EMIF signal multiplexing, see the I/O Multiplexing Module chapter of the technical reference manual.

21.2.12 Memory Map

For information describing the device memory-map, see your device-specific datasheet.

Copyright © 2018, Texas Instruments Incorporated

21.2.13 Priority and Arbitration

Section 21.2.2 describes the external prioritization and arbitration among requests from different sources within the microcontroller. The result of this external arbitration is that only one request is presented to the EMIF at a time. Once the EMIF completes a request, the external arbiter then provides the EMIF with the next pending request.

Internally, the EMIF undertakes memory device transactions according to a strict priority scheme. The highest priority events are:

- A device reset.
- A write to any of the three least significant bytes of the SDRAM configuration register (SDCR).

Either of these events will cause the EMIF to immediately commence its initialization sequence as described in Section 21.2.5.4.

Once the EMIF has completed its initialization sequence, it performs memory transactions according to the following priority scheme (highest priority listed first):

1. If the EMIF's backlog refresh counter is at the Refresh Must urgency level, the EMIF performs multiple SDRAM auto refresh cycles until the Refresh Release urgency level is reached.
2. If an SDRAM or asynchronous read has been requested, the EMIF performs a read operation.
3. If the EMIF's backlog refresh counter is at the Refresh Need urgency level, the EMIF performs an SDRAM auto refresh cycle.
4. If an SDRAM or asynchronous write has been requested, the EMIF performs a write operation.
5. If the EMIF's backlog refresh counter is at the Refresh May or Refresh Release urgency level, the EMIF performs an SDRAM auto refresh cycle.
6. If the value of the SR bit in SDCR has been set to 1, the EMIF will enter the self-refresh state as described in Section 21.2.5.7.

After taking one of the actions listed above, the EMIF then returns to the top of the priority list to determine its next action.

Because the EMIF does not issue auto-refresh cycles when in the self-refresh state, the above priority scheme does not apply when in this state. See Section 21.2.5.7 for details on the operation of the EMIF when in the self-refresh state.

21.2.14 System Considerations

This section describes various system considerations to keep in mind when operating the EMIF.

21.2.14.1 Asynchronous Request Times

In a system that interfaces to both SDRAM and asynchronous memory, the asynchronous requests must not take longer than the smaller of the following two values:

- t_{RAS} (typically 120 μs) - to avoid violating the maximum time allowed between issuing an ACTV and PRE command to the SDRAM.
- $t_{Refresh\ Rate}$ × 11 (typically 15.7 μs × 11 = 172.7 μs) - to avoid refresh violations on the SDRAM.
  The length of an asynchronous request is controlled by multiple factors, the primary factor being the number of access cycles required to complete the request. For example, an asynchronous request for 4 bytes will require four access cycles using an 8-bit data bus and only two access cycle using a 16-bit data bus. The maximum request size that the EMIF can be sent is 16 words, therefore the maximum number of access cycles per memory request is 64 when the EMIF is configured with an 8-bit data bus. The length of the individual access cycles that make up the asynchronous request is determined by the programmed setup, strobe, hold, and turnaround values, but can also be extended with the assertion of the EMIF_nWAIT input signal up to a programmed maximum limit. It is up to the user to make sure that an entire asynchronous request does not exceed the timing values listed above when also interfacing to an SDRAM device. This can be done by limiting the asynchronous timing parameters.

21.2.14.2 Interface to External Peripheral or FIFO Memory

If EMIF is used to interface to an external peripheral or FIFO logic (for example, UHPI), it is recommended to use the host CPU's Memory Protection Unit (MPU) to define this external memory range as a region that is either strongly-ordered or of device type.

21.2.14.3 Interface to External SDRAM

If EMIF is used to interface to an external SDRAM, it is recommended to burst as much as possible to normal memory to improve the interface bandwidth.

Copyright © 2018, Texas Instruments Incorporated

21.2.15 Power Management

Power dissipation from the EMIF memory controller may be managed by following methods:

- Self-refresh mode
- Power-down mode
- Gating input clocks to the module off

Gating input clocks off to the EMIF memory controller achieves higher power savings when compared to the power savings of self-refresh or power down mode. The input clock VCLK3 can be turned off through the use of the Global Clock Module (GCM). Before gating clocks off, the EMIF memory controller must place the SDR SDRAM memory in self-refresh mode. If the external memory requires a continuous clock, the VCLK3 clock domain must not be turned off because this may result in data corruption. See the following subsections for the proper procedures to follow when stopping the EMIF memory controller clocks.

21.2.15.1 Power Management Using Self-Refresh Mode

The EMIF can be placed into a self-refresh state in order to place the attached SDRAM devices into self-refresh mode, which consumes less power for most SDRAM devices. In this state, the attached SDRAM device uses an internal clock to perform its own auto refresh cycles. This maintains the validity of the data in the SDRAM without the need for any external commands. Refer to Section 21.2.5.7 for more details on placing the EMIF into the self-refresh state.

21.2.15.2 Power Management Using Power Down Mode

In the power down mode, EMIF drives EMIF_CKE low to lower the power consumption. EMIF_CKE goes high when there is a need to send refresh (REFR) commands, after which EMIF_CKE is again driven low. EMIF_CKE remains low until any request arrives. Refer to Section 21.2.5.8 for more details on placing EMIF in power down mode.

21.2.16 Emulation Considerations

EMIF memory controller remains fully functional during emulation halts in order to allow emulation access to external memory.

Copyright © 2018, Texas Instruments Incorporated

21.3 EMIF Registers

The external memory interface (EMIF) is controlled by programming its internal memory-mapped registers (MMRs). Table 21-24 lists the memory-mapped registers for the EMIF.

NOTE: All EMIF MMRs, except SDCR, support only word (32-bit) accesses. Performing a byte (8-bit) or halfword (16-bit) write to these registers results in undefined behavior. The SDCR is byte writable to allow the setting of the SR, PD, and PDWR bits without triggering the SDRAM initialization sequence.

The EMIF registers must always be accessed using 32-bit accesses (unless otherwise specified in this chapter). The base address of the EMIF memory-mapped registers is FCFF E800h.

Table 21-24. External Memory Interface (EMIF) Registers

Offset	Acronym	Register Description	Section
00h	MIDR	Module ID Register	Section 21.3.1
04h	AWCC	Asynchronous Wait Cycle Configuration Register	Section 21.3.2

21.3.2 Asynchronous Wait Cycle Configuration Register (AWCC)

The asynchronous wait cycle configuration register (AWCC) is used to configure the parameters for extended wait cycles. Both the polarity of the EMIF_nWAIT pin(s) and the maximum allowable number of extended wait cycles can be configured. The AWCC is shown in Figure 21-16 and described in Table 21-26. Not all devices support both EMIF_nWAIT[1] and EMIF_nWAIT[0], see the device-specific data manual to determine support on each device.

NOTE: The EW bit in the asynchronous *n* configuration register (CE*n*CFG) must be set to allow for the insertion of extended wait cycles.

Figure 21-16. Asynchronous Wait Cycle Configuration Register (AWCCR) [offset = 04h]

Table 21-26. Asynchronous Wait Cycle Configuration Register (AWCCR) Field Descriptions

Bit	Field	Value	Description
31-30	Reserved	3h	Reserved
29	WP1		EMIF_nWAIT[1] polarity bit. This bit defines the polarity of the EMIF_nWAIT[1] pin.
		0	Insert wait cycles if EMIF_nWAIT[1] pin is low.
		1	Insert wait cycles if EMIF_nWAIT[1] pin is high.
28	WP0		EMIF_nWAIT[0] polarity bit. This bit defines the polarity of the EMIF_nWAIT[0] pin.
		0	Insert wait cycles if EMIF_nWAIT[0] pin is low.
		1	Insert wait cycles if EMIF_nWAIT[0] pin is high.
27-24	Reserved	0	Reserved
23-22	CS5_WAIT	0-3h	Chip Select 5 WAIT signal selection. This signal determines which EMIF_nWAIT[*n*] signal will be used for memory accesses to chip select 5 memory space. This device does not support chip select 5, so any value written to this field has no effect.
21-20	CS4_WAIT		Chip Select 4 WAIT signal selection. This signal determines which EMIF_nWAIT[*n*] signal will be used for memory accesses to chip select 4 memory space.
		0	EMIF_nWAIT[0] pin is used to control external wait states.
		1h	EMIF_nWAIT[1] pin is used to control external wait states.
		2h-3h	Reserved
19-18	CS3_WAIT		Chip Select 3 WAIT signal selection. This signal determines which EMIF_nWAIT[*n*] signal will be used for memory accesses to chip select 3 memory space.
		0	EMIF_nWAIT[0] pin is used to control external wait states.
		1h	EMIF_nWAIT[1] pin is used to control external wait states.
		2h-3h	Reserved
17-16	CS2_WAIT		Chip Select 2 WAIT signal selection. This signal determines which EMIF_nWAIT[*n*] signal will be used for memory accesses to chip select 2 memory space.
		0	EMIF_nWAIT[0] pin is used to control external wait states..
		1h	EMIF_nWAIT[1] pin is used to control external wait states.
		2h-3h	Reserved
15-8	Reserved	0	Reserved
7-0	MAX_EXT_WAIT	0-FFh	Maximum extended wait cycles. The EMIF will wait for a maximum of (MAX_EXT_WAIT + 1) × 16 clock cycles before it stops inserting asynchronous wait cycles and proceeds to the hold period of the access.

21.3.3 SDRAM Configuration Register (SDCR)

The SDRAM configuration register (SDCR) is used to configure various parameters of the SDRAM controller such as the number of internal banks, the internal page size, and the CAS latency to match those of the attached SDRAM device. In addition, this register is used to put the attached SDRAM device into Self-Refresh mode. The SDCR is shown in Figure 21-17 and described in Table 21-27.

NOTE: Writing to the lower three bytes of this register will cause the EMIF to start the SDRAM initialization sequence described in Section 21.2.5.4.

Figure 21-17. SDRAM Configuration Register (SDCR) [offset = 08h]

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

A. The NM bit must be set to 1 if the EMIF on your device only has 16 data bus pins.

Table 21-27. SDRAM Configuration Register (SDCR) Field Descriptions

Bit	Field	Value	Description
31	SR		Self-Refresh mode bit. This bit controls entering and exiting of the Self-Refresh mode described in Section 21.2.5.7. The field should be written using a byte-write to the upper byte of SDCR to avoid triggering the SDRAM initialization sequence.
		0	Writing a 0 to this bit will cause connected SDRAM devices and the EMIF to exit the Self-Refresh mode.
		1	Writing a 1 to this bit will cause connected SDRAM devices and the EMIF to enter the Self-Refresh mode.
30	PD		Power Down bit. This bit controls entering and exiting of the power-down mode. The field should be written using a byte-write to the upper byte of SDCR to avoid triggering the SDRAM initialization sequence. If both SR and PD bits are set, the EMIF will go into Self Refresh.
		0	Writing a 0 to this bit will cause connected SDRAM devices and the EMIF to exit the power-down mode.
		1	Writing a 1 to this bit will cause connected SDRAM devices and the EMIF to enter the power-down mode.
29	PDWR		Perform refreshes during power down. Writing a 1 to this bit will cause EMIF to exit power-down state and issue and AUTO REFRESH command every time Refresh May level is set.
28-15	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
14	NM		Narrow mode bit. This bit defines whether a 16- or 32-bit-wide SDRAM is connected to the EMIF. This bit field must always be set to 1. Writing to this field triggers the SDRAM initialization sequence.
		0	32-bit SDRAM data bus is used.
		1	16-bit SDRAM data bus is used.
13-12	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.

Table 21-27. SDRAM Configuration Register (SDCR) Field Descriptions (continued)

Bit	Field	Value	Description
11-9	CL		CAS Latency. This field defines the CAS latency to be used when accessing connected SDRAM devices. A 1 must be simultaneously written to the BIT11_9LOCK bit field of this register in order to write to the CL bit field. Writing to this field triggers the SDRAM initialization sequence.
		0-1h	Reserved
		2h	CAS latency = 2 EMIF_CLK cycles
		3h	CAS latency = 3 EMIF_CLK cycles
		4h-7h	Reserved
8	BIT11_9LOCK		Bits 11 to 9 lock. CL can only be written if BIT11_9LOCK is simultaneously written with a 1. BIT11_9LOCK is always read as 0. Writing to this field triggers the SDRAM initialization sequence.
		0	CL cannot be written.
		1	CL can be written.
7	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
6-4	IBANK		Internal SDRAM Bank size. This field defines number of banks inside the connected SDRAM devices. Writing to this field triggers the SDRAM initialization sequence.
		0	1 bank SDRAM devices.
		1	2 bank SDRAM devices.
		2	4 bank SDRAM devices.
		3h-7h	Reserved.
3	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
2-0	PAGESIZE		Page Size. This field defines the internal page size of connected SDRAM devices. Writing to this field triggers the SDRAM initialization sequence.
		0	8 column address bits (256 elements per row)
		1h	9 column address bits (512 elements per row)
		2h	10 column address bits (1024 elements per row)
		3h	11 column address bits (2048 elements per row)
		4h-7h	Reserved

21.3.4 SDRAM Refresh Control Register (SDRCR)

The SDRAM refresh control register (SDRCR) is used to configure the rate at which connected SDRAM devices will be automatically refreshed by the EMIF. Refer to Section 21.2.5.6 on the refresh controller for more details. The SDRCR is shown in Figure 21-18 and described in Table 21-28.

Figure 21-18. SDRAM Refresh Control Register (SDRCR) [offset = 0Ch]

21.3.5 Asynchronous *n* Configuration Registers (CE2CFG-CE5CFG)

The asynchronous *n* configuration registers (CE2CFG, CE3CFG, CE4CFG, and CE5CFG) are used to configure the shaping of the address and control signals during an access to asynchronous memory connected to CS2, CS3, CS4, and CS5, respectively. CS5 is not available on this device. It is also used to program the width of asynchronous interface and to select from various modes of operation. This register can be written prior to any transfer, and any asynchronous transfer following the write will use the new configuration. The CE*n*CFG is shown in Figure 21-19 and described in Table 21-29.

Figure 21-19. Asynchronous *n* Configuration Register (CE*n*CFG) [offset = 10h - 1Ch]

31	30	29 26	25 24

A. The EW bit must be cleared to 0.

B. This bit field must be cleared to 0 if the EMIF on your device does not have an EMIF_nWAIT pin.

Table 21-29. Asynchronous *n* Configuration Register (CE*n*CFG) Field Descriptions

Bit	Field	Value	Description
31	SS		Select Strobe bit. This bit defines whether the asynchronous interface operates in Normal Mode or Select Strobe Mode. See Section 21.2.6 for details on the two modes of operation.
		0	Normal Mode enabled.
		1	Select Strobe Mode enabled.
30	EW		Extend Wait bit. This bit defines whether extended wait cycles will be enabled. See Section 21.2.6.6 on extended wait cycles for details. This bit field must be set to 0, if the EMIF on your device does not have an EMIF_nWAIT pin.
		0	Extended wait cycles disabled.
		1	Extended wait cycles enabled.
29-26	W_SETUP	0-Fh	Write setup width in EMIF_CLK cycles, minus one cycle. See Section 21.2.6.3 for details.
25-20	W_STROBE	0-3Fh	Write strobe width in EMIF_CLK cycles, minus one cycle. See Section 21.2.6.3 for details.
19-17	W_HOLD	0-7h	Write hold width in EMIF_CLK cycles, minus one cycle. See Section 21.2.6.3 for details.
16-13	R_SETUP	0-Fh	Read setup width in EMIF_CLK cycles, minus one cycle. See Section 21.2.6.3 for details.
12-7	R_STROBE	0-3Fh	Read strobe width in EMIF_CLK cycles, minus one cycle. See Section 21.2.6.3 for details.
6-4	R_HOLD	0-7h	Read hold width in EMIF_CLK cycles, minus one cycle. See Section 21.2.6.3 for details.
3-2	TA	0-3h	Minimum Turn-Around time. This field defines the minimum number of EMIF_CLK cycles between reads and writes, minus one cycle. See Section 21.2.6.3 for details.
1-0	ASIZE		Asynchronous Data Bus Width. This field defines the width of the asynchronous device's data bus.
		0	8-bit data bus
		1h	16-bit data bus
		2h-3h	Reserved

21.3.6 SDRAM Timing Register (SDTIMR)

The SDRAM timing register (SDTIMR) is used to program many of the SDRAM timing parameters. Consult the SDRAM datasheet for information on the appropriate values to program into each field. The SDTIMR is shown in Figure 21-20 and described in Table 21-30.

Figure 21-20. SDRAM Timing Register (SDTIMR) [offset = 20h]

31–27	26–24	23	22–20	19	18–16

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-30. SDRAM Timing Register (SDTIMR) Field Descriptions

Bit	Field	Value	Description
31-27	T_RFC	0-1Fh	Specifies the Trfc value of the SDRAM. This defines the minimum number of EMIF_CLK cycles from Refresh (REFR) to Refresh (REFR), minus 1: T_RFC = (Trfc/t_{EMIF_CLK}) - 1
26-24	T_RP	0-7h	Specifies the Trp value of the SDRAM. This defines the minimum number of EMIF_CLK cycles from Precharge (PRE) to Activate (ACTV) or Refresh (REFR) command, minus 1: T_RP = (Trp/t_{EMIF_CLK}) - 1
23	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
22-20	T_RCD	0-7h	Specifies the Trcd value of the SDRAM. This defines the minimum number of EMIF_CLK cycles from Active (ACTV) to Read (READ) or Write (WRT), minus 1: T_RCD = (Trcd/t_{EMIF_CLK}) - 1
19	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
18-16	T_WR	0-7h	Specifies the Twr value of the SDRAM. This defines the minimum number of EMIF_CLK cycles from last Write (WRT) to Precharge (PRE), minus 1: T_WR = (Twr/t_{EMIF_CLK}) - 1
15-12	T_RAS	0-Fh	Specifies the Tras value of the SDRAM. This defines the minimum number of EMIF_CLK clock cycles from Activate (ACTV) to Precharge (PRE), minus 1: T_RAS = (Tras/t_{EMIF_CLK}) - 1
11-8	T_RC	0-Fh	Specifies the Trc value of the SDRAM. This defines the minimum number of EMIF_CLK clock cycles from Activate (ACTV) to Activate (ACTV), minus 1: T_RC = (Trc/t_{EMIF_CLK}) - 1
7	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
6-4	T_RRD	0-7h	Specifies the Trrd value of the SDRAM. This defines the minimum number of EMIF_CLK clock cycles from Activate (ACTV) to Activate (ACTV) for a different bank, minus 1: T_RRD = (Trrd/t_{EMIF_CLK}) - 1
3-0	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.

Copyright © 2018, Texas Instruments Incorporated

21.3.7 SDRAM Self Refresh Exit Timing Register (SDSRETR)

The SDRAM self refresh exit timing register (SDSRETR) is used to program the amount of time between when the SDRAM exits Self-Refresh mode and when the EMIF issues another command. The SDSRETR is shown in Figure 21-21 and described in Table 21-31.

21.3.8 EMIF Interrupt Raw Register (INTRAW)

The EMIF interrupt raw register (INTRAW) is used to monitor and clear the EMIF's hardware-generated Asynchronous Timeout Interrupt. The AT bit in this register will be set when an Asynchronous Timeout occurs regardless of the status of the EMIF interrupt mask set register (INTMSKSET) and EMIF interrupt mask clear register (INTMSKCLR). Writing a 1 to this bit will clear it. The EMIF on some devices does not have the EMIF_nWAIT pin; therefore, these registers and fields are reserved on those devices. The INTRAW is shown in Figure 21-22 and described in Table 21-32.

Table 21-32. EMIF Interrupt Raw Register (INTRAW) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
2	WR		Wait Rise. This bit is set to 1 by hardware to indicate that a rising edge on the EMIF_nWAIT pin has occurred.
		0	Indicates that a rising edge has not occurred on the EMIF_nWAIT pin. Writing a 0 has no effect.
		1	Indicates that a rising edge has occurred on the EMIF_nWAIT pin. Writing a 1 will clear this bit and the WR_MASKED bit in the EMIF interrupt masked register (INTMSK).
1	LT		Line Trap. Set to 1 by hardware to indicate illegal memory access type or invalid cache line size.
		0	Writing a 0 has no effect.
		1	Indicates that a line trap has occurred. Writing a 1 will clear this bit as well as the LT_MASKED bit in the EMIF interrupt masked register(INTMSK).
0	AT		Asynchronous Timeout. This bit is set to 1 by hardware to indicate that during an extended asynchronous memory access cycle, the EMIF_nWAIT pin did not go inactive within the number of cycles defined by the MAX_EXT_WAIT field in the asynchronous wait cycle configuration register (AWCC).
		0	Indicates that an Asynchronous Timeout has not occurred. Writing a 0 has no effect.
		1	Indicates that an Asynchronous Timeout has occurred. Writing a 1 will clear this bit as well as the AT_MASKED bit in the EMIF interrupt masked register (INTMSK).

Copyright © 2018, Texas Instruments Incorporated

21.3.9 EMIF Interrupt Masked Register (INTMSK)

Like the EMIF interrupt raw register (INTRAW), the EMIF interrupt masked register (INTMSK) is used to monitor and clear the status of the EMIF's hardware-generated Asynchronous Timeout Interrupt. The main difference between the two registers is that when the AT_MASKED bit in this register is set, an active-high pulse will be sent to the CPU interrupt controller. Also, the AT_MASKED bit field in INTMSK is only set to 1 if the associated interrupt has been enabled in the EMIF interrupt mask set register (INTMSKSET). The EMIF on some devices does not have the EMIF_nWAIT pin, therefore, these registers and fields are reserved on those devices. The INTMSK is shown in Figure 21-23 and described in Table 21-33.

Table 21-33. EMIF Interrupt Mask Register (INTMSK) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
2	WR_MASKED		Wait Rise Masked. This bit is set to 1 by hardware to indicate a rising edge has occurred on the EMIF_nWAIT pin, provided that the WR_MASK_SET bit is set to 1 in the EMIF interrupt mask set register (INTMSKSET).
		0	Indicates that a wait rise interrupt has not been generated. Writing a 0 has no effect.
		1	Indicates that a wait rise interrupt has been generated. Writing a 1 will clear this bit and the WR bit in the EMIF interrupt raw register (INTRAW).
1	LT_MASKED		Masked Line Trap. Set to 1 by hardware to indicate illegal memory access type or invalid cache line size, only if the LT_MASK_SET bit in the EMIF interrupt mask set register (INTMSKSET) is set to 1.
		0	Writing a 0 has no effect.
		1	Writing a 1 will clear this bit as well as the LT bit in the EMIF interrupt raw register(INTRAW).
0	AT_MASKED		Asynchronous Timeout Masked. This bit is set to 1 by hardware to indicate that during an extended asynchronous memory access cycle, the EMIF_nWAIT pin did not go inactive within the number of cycles defined by the MAX_EXT_WAIT field in the asynchronous wait cycle configuration register (AWCC), provided that the AT_MASK_SET bit is set to 1 in the EMIF interrupt mask set register (INTMSKSET).
		0	Indicates that an Asynchronous Timeout Interrupt has not been generated. Writing a 0 has no effect.
		1	Indicates that an Asynchronous Timeout Interrupt has been generated. Writing a 1 will clear this bit as well as the AT bit in the EMIF interrupt raw register (INTRAW).

Copyright © 2018, Texas Instruments Incorporated

21.3.10 EMIF Interrupt Mask Set Register (INTMSKSET)

The EMIF interrupt mask set register (INTMSKSET) is used to enable the Asynchronous Timeout Interrupt. If read as 1, the AT_MASKED bit in the EMIF interrupt masked register (INTMSK) will be set and an interrupt will be generated when an Asynchronous Timeout occurs. If read as 0, the AT_MASKED bit will always read 0 and no interrupt will be generated when an Asynchronous Timeout occurs. Writing a 1 to the AT_MASK_SET bit enables the Asynchronous Timeout Interrupt. The EMIF on some devices does not have the EMIF_nWAIT pin; therefore, these registers and fields are reserved on those devices. The INTMSKSET is shown in Figure 21-24 and described in Table 21-34.

Table 21-34. EMIF Interrupt Mask Set Register (INTMSKSET) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
2	WR_MASK_SET		Wait Rise Mask Set. This bit determines whether or not the wait rise Interrupt is enabled. Writing a 1 to this bit sets this bit, sets the WR_MASK_CLR bit in the EMIF interrupt mask clear register (INTMSKCLR), and enables the wait rise interrupt. To clear this bit, a 1 must be written to the WR_MASK_CLR bit in INTMSKCLR.
		0	Indicates that the wait rise interrupt is disabled. Writing a 0 has no effect.
		1	Indicates that the wait rise interrupt is enabled. Writing a 1 sets this bit and the WR_MASK_CLR bit in the EMIF interrupt mask clear register (INTMSKCLR).
1	LT_MASK_SET		Mask set for LT_MASKED bit in the EMIF interrupt mask register (INTMSK).
		0	Indicates that the line trap interrupt is disabled. Writing a 0 has no effect.
		1	Indicates that the line trap interrupt is enabled. Writing a 1 sets this bit and the LT_MASK_CLR bit in the EMIF interrupt mask clear register (INTMSKCLR).
0	AT_MASK_SET		Asynchronous Timeout Mask Set. This bit determines whether or not the Asynchronous Timeout Interrupt is enabled. Writing a 1 to this bit sets this bit, sets the AT_MASK_CLR bit in the EMIF interrupt mask clear register (INTMSKCLR), and enables the Asynchronous Timeout Interrupt. To clear this bit, a 1 must be written to the AT_MASK_CLR bit of the EMIF interrupt mask clear register (INTMSKCLR).
		0	Indicates that the Asynchronous Timeout Interrupt is disabled. Writing a 0 has no effect.
		1	Indicates that the Asynchronous Timeout Interrupt is enabled. Writing a 1 sets this bit and the AT_MASK_CLR bit in the EMIF interrupt mask clear register (INTMSKCLR).

Copyright © 2018, Texas Instruments Incorporated

21.3.11 EMIF Interrupt Mask Clear Register (INTMSKCLR)

The EMIF interrupt mask clear register (INTMSKCLR) is used to disable the Asynchronous Timeout Interrupt. If read as 1, the AT_MASKED bit in the EMIF interrupt masked register (INTMSK) will be set and an interrupt will be generated when an Asynchronous Timeout occurs. If read as 0, the AT_MASKED bit will always read 0 and no interrupt will be generated when an Asynchronous Timeout occurs. Writing a 1 to the AT_MASK_CLR bit disables the Asynchronous Timeout Interrupt. The EMIF on some devices does not have the EMIF_nWAIT pin, therefore, these registers and fields are reserved on those devices. The INTMSKCLR is shown in Figure 21-25 and described in Table 21-35.

Table 21-35. EMIF Interrupt Mask Clear Register (INTMSKCLR) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reserved. The reserved bit location is always read as 0. If writing to this field, always write the default value of 0.
2	WR_MASK_CLR		Wait Rise Mask Clear. This bit determines whether or not the wait rise interrupt is enabled. Writing a 1 to this bit clears this bit, clears the WR_MASK_SET bit in the EMIF interrupt mask set register (INTMSKSET), and disables the wait rise interrupt. To set this bit, a 1 must be written to the WR_MASK_SET bit in INTMSKSET.
		0	Indicates that the wait rise interrupt is disabled. Writing a 0 has no effect.
		1	Indicates that the wait rise interrupt is enabled. Writing a 1 clears this bit and the WR_MASK_SET bit in the EMIF interrupt mask set register (INTMSKSET).
1	LT_MASK_CLR		Line trap Mask Clear. This bit determines whether or not the line trap interrupt is enabled. Writing a 1 to this bit clears this bit, clears the LT_MASK_SET bit in the EMIF interrupt mask set register (INTMSKSET), and disables the line trap interrupt. To set this bit, a 1 must be written to the LT_MASK_SET bit in INTMSKSET.
		0	Indicates that the line trap interrupt is disabled. Writing a 0 has no effect.
		1	Indicates that the line trap interrupt is enabled. Writing a 1 clears this bit and the LT_MASK_SET bit in the EMIF interrupt mask set register (INTMSKSET).
0	AT_MASK_CLR		Asynchronous Timeout Mask Clear. This bit determines whether or not the Asynchronous Timeout Interrupt is enabled. Writing a 1 to this bit clears this bit, clears the AT_MASK_SET bit in the EMIF interrupt mask set register (INTMSKSET), and disables the Asynchronous Timeout Interrupt. To set this bit, a 1 must be written to the AT_MASK_SET bit of the EMIF interrupt mask set register (INTMSKSET).
		0	Indicates that the Asynchronous Timeout Interrupt is disabled. Writing a 0 has no effect.
		1	Indicates that the Asynchronous Timeout Interrupt is enabled. Writing a 1 clears this bit and the AT_MASK_SET bit in the EMIF interrupt mask set register (INTMSKSET).

21.4 Example Configuration

This section presents an example of interfacing the EMIF to both an SDR SDRAM device and an asynchronous flash device.

21.4.1 Hardware Interface

Figure 21-27 shows the hardware interface between the EMIF, a Samsung K4S641632H-TC(L)70 64Mb SDRAM device, and two SHARP LH28F800BJE-PTTL90 8Mb Flash memory. The connection between the EMIF and the SDRAM is straightforward, but the connection between the EMIF and the flash deserves a detailed look.

The address inputs for the flash are provided by three sources. The A[18:0] address inputs are provided by a combination of the EMIF_A and EMIF_BA pins according to Section 21.2.6.1. RD/nBY signal from one flash is connected to EMIF_nWAIT pin of EMIF.

Finally, this example configuration connects the EMIF_nWE pin to the nWE input of the flash and operates the EMIF in Select Strobe Mode.

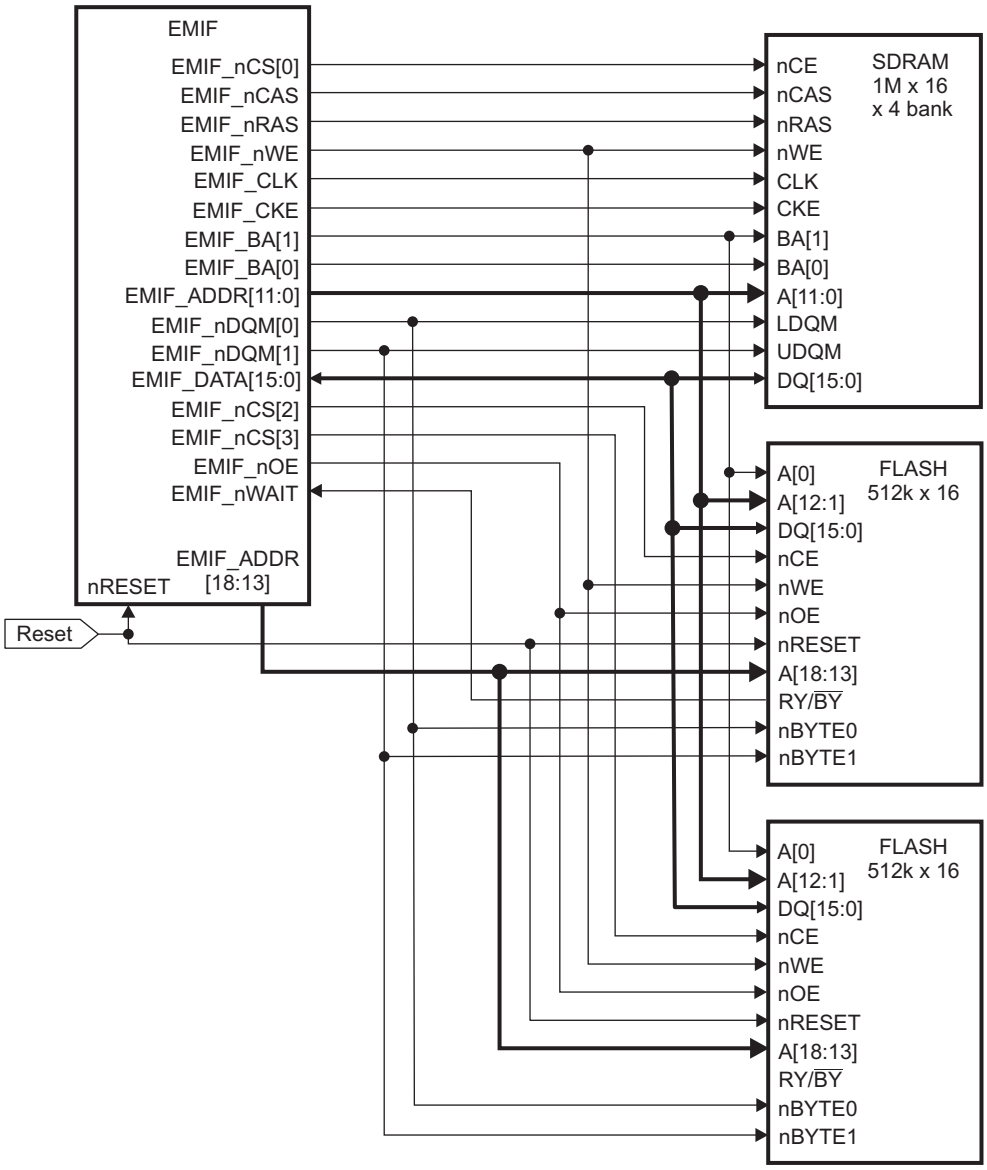
21.4.2 Software Configuration

The following sections describe how to configure the EMIF registers and bit fields to interface the EMIF with the Samsung K4S641632H-TC(L)70 SDRAM and the SHARP LH28F800BJE-PTTL90 8Mb Flash memory.

21.4.2.1 Configuring the SDRAM Interface

This section describes how to configure the EMIF to interface with the Samsung K4S641632H-TC(L)70 SDRAM with a clock frequency of f_{EMIF_CLK} = 100 MHz. Procedure A described in Section 21.2.5.5 is followed which assumes that the SDRAM power-up timing constraint were met during the SDRAM Auto-Initialization sequence after Reset.

21.4.2.1.1 PLL Programming for the EMIF to K4S641632H-TC(L)70 Interface



The device global clock module (GCM) should first be programmed to select the desired EMIF_CLK frequency. Before doing this, the SDRAM should be placed in Self-Refresh Mode by setting the SR bit in the SDRAM configuration register (SDCR). The SR bit should be set using a byte-write to the upper byte of the SDCR to avoid triggering the SDRAM Initialization Sequence. The EMIF_CLK frequency can now be configured to the desired value by selecting the appropriate clock source for the VCLK3 domain. Once the VCLK3 domain frequency has been configured, remove the SDRAM from Self-Refresh by clearing the SR bit in SDCR, again with a byte-write.

Table 21-37. SR Field Value For the EMIF to K4S641632H-TC(L)70 Interface

Field	Value	Purpose
SR	1 then 0	To place the EMIF into the self refresh state

21.4.2.1.2 SDRAM Timing Register (SDTIMR) Settings for the EMIF to K4S641632H-TC(L)70 Interface

The fields of the SDRAM timing register (SDTIMR) should be programmed first as described in Table 21-38 to satisfy the required timing parameters for the K4S641632H-TC(L)70. Based on these calculations, a value of 6111 4610h should be written to SDTIMR. Figure 21-28 shows a graphical description of how SDTIMR should be programmed.

Table 21-38. SDTIMR Field Calculations for the EMIF to K4S641632H-TC(L)70 Interface

Field Name	Formula	Value from K4S641632H-TC(L)70 Datasheet	Value Calculated for Field
T_RFC	T_RFC >= (t_{RFC} × f_{EMIF_CLK}) - 1	t_{RC} = 68 ns (min)(1)	6
T_RP	T_RP >= (t_{RP} × f_{EMIF_CLK}) - 1	t_{RP} = 20 ns (min)	1
T_RCD	T_RCD >= (t_{RCD} × f_{EMIF_CLK}) - 1	t_{RCD} = 20 ns (min)	1
T_WR	T_WR >= (t_{WR} × f_{EMIF_CLK}) - 1	t_{RDL} = 2 CLK = 20 ns (min)(2)	1
T_RAS	T_RAS >= (t_{RAS} × f_{EMIF_CLK}) - 1	t_{RAS} = 49 ns (min)	4
T_RC	T_RC >= (t_{RC} × f_{EMIF_CLK}) - 1	t_{RC} = 68 ns (min)	6
T_RRD	T_RRD >= (t_{RRD} × f_{EMIF_CLK}) - 1	t_{RRD} = 14 ns (min)	1

(1) The Samsung datasheet does not specify a t_{RFC} value. Instead, Samsung specifies t_{RC} as the minimum auto refresh period.
(2) The Samsung datasheet does not specify a t_{WR} value. Instead, Samsung specifies t_{RDL} as last data in to row precharge minimum delay.

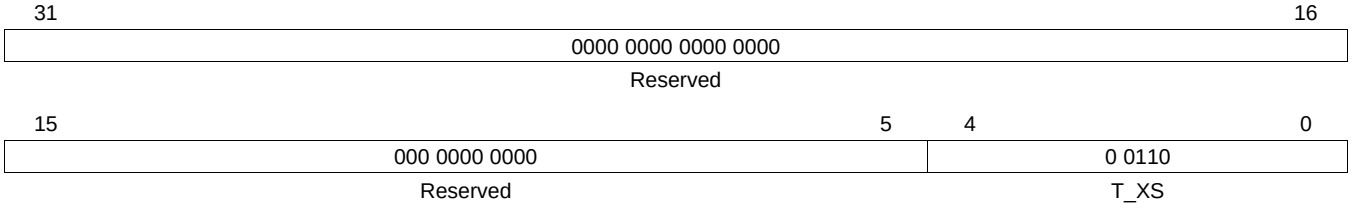
21.4.2.1.3 SDRAM Self Refresh Exit Timing Register (SDSRETR) Settings for the EMIF to K4S641632H-TC(L)70 Interface



The SDRAM self refresh exit timing register (SDSRETR) should be programmed second to satisfy the t_{XSR} timing requirement from the K4S641632H-TC(L)70 datasheet. Table 21-39 shows the calculation of the proper value to program into the T_XS field of this register. Based on this calculation, a value of 6h should be written to SDSRETR. Figure 21-29 shows how SDSRETR should be programmed.

Table 21-39. RR Calculation for the EMIF to K4S641632H-TC(L)70 Interface

Field Name	Formula	Value from K4S641632H-TC(L)70 Datasheet	Value Calculated for Field
T_XS	T_XS >= (t_{XSR} × f_{EMIF_CLK}) - 1	t_{RC} = 68 ns (min)[1]	6

(1) The Samsung datasheet does not specify a t_{XSR} value. Instead, Samsung specifies t_{RC} as the minimum required time after CKE going high to complete self refresh exit.

Figure 21-29. SDRAM Self Refresh Exit Timing Register (SDSRETR)

21.4.2.1.4 SDRAM Refresh Control Register (SDRCR) Settings for the EMIF to K4S641632H-TC(L)70 Interface

The SDRAM refresh control register (SDRCR) should next be programmed to satisfy the required refresh rate of the K4S641632H-TC(L)70. Table 21-40 shows the calculation of the proper value to program into the RR field of this register. Based on this calculation, a value of 61Ah should be written to SDRCR. Figure 21-30 shows how SDRCR should be programmed.

Table 21-40. RR Calculation for the EMIF to K4S641632H-TC(L)70 Interface

Field Name	Formula	Values	Value Calculated for Field
RR	RR ≤ f_{EMIF_CLK} × $t_{Refresh\ Period}$ / n_{cycles}	From SDRAM datasheet: $t_{Refresh\ Period}$ = 64 ms; n_{cycles} = 4096 EMIF clock rate: f_{EMIF_CLK} = 100 MHz	RR = 1562 cycles = 61Ah cycles

Copyright © 2018, Texas Instruments Incorporated

21.4.2.1.5 SDRAM Configuration Register (SDCR) Settings for the EMIF to K4S641632H-TC(L)70 Interface

Finally, the fields of the SDRAM configuration register (SDCR) should be programmed as described in Table 21-37 to properly interface with the K4S641632H-TC(L)70 device. Based on these settings, a value of 4720h should be written to SDCR. Figure 21-31 shows how SDCR should be programmed. The EMIF is now ready to perform read and write accesses to the SDRAM.

Table 21-41. SDCR Field Values For the EMIF to K4S641632H-TC(L)70 Interface

Field	Value	Purpose
SR	0	To avoid placing the EMIF into the self refresh state
NM	1	To configure the EMIF for a 16-bit data bus
CL	011b	To select a CAS latency of 3
BIT11_9LOCK	1	To allow the CL field to be written
IBANK	010b	To select 4 internal SDRAM banks
PAGESIZE	0	To select a page size of 256 words

21.4.2.2 Configuring the Flash Interface

This section describes how to configure the EMIF to interface with the two of SHARP LH28F800BJE-PTTL90 8Mb Flash memory with a clock frequency of f_{EMIF_CLK} = 100 MHz. The example assumes that one flash is connected to EMIF_nCS2 and the other to EMIF_nCS3.

21.4.2.2.1 Asynchronous 1 Configuration Register (CE2CFG) Settings for the EMIF to LH28F800BJE-PTTL90 Interface

The asynchronous 1 configuration register (CE2CFG) and asynchronous 2 configuration register (CE3CFG) are the only registers that is necessary to program for this asynchronous interface (assuming that one Flash is connected to EMIF_nCS[2] and the other to EMIF_nCS[3]. The SS bit (in both registers) should be set to 1 to enable Select Strobe Mode and the ASIZE field (in both registers) should be set to 1 to select a 16-bit interface. The other fields in this register control the shaping of the EMIF signals, and the proper values can be determined by referring to the AC Characteristics in the Flash datasheet and the device datasheet. Based on the following calculations, a value of 8862 25BDh should be written to CE2CFG. Table 21-42 and Table 21-43 show the pertinent AC Characteristics for reads and writes to the Flash device, and Figure 21-32 and Figure 21-33 show the associated timing waveforms. Finally, Figure 21-34 shows programming the CE*n*CFG (*n* = 2, 3) with the calculated values.

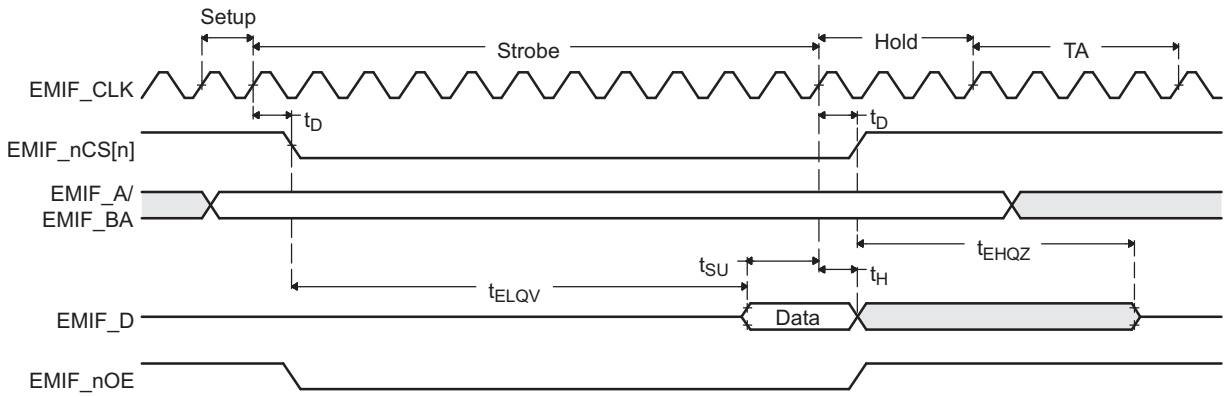

Table 21-42. AC Characteristics for a Read Access

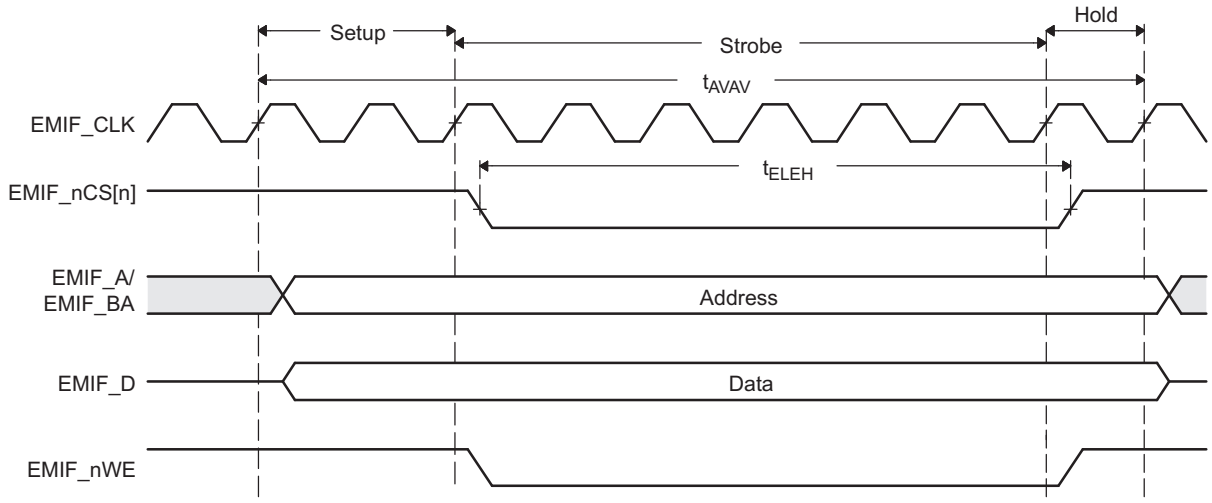
AC Characteristic	Device	Definition	Min	Max	Unit
t_{SU}	EMIF	Setup time, read EMIF_D before EMIF_CLK high	6.5		ns
t_H	EMIF	Data hold time, read EMIF_D after EMIF_CLK high	1		ns
t_D	EMIF	Output delay time, EMIF_CLK high to output signal valid		7	ns
t_{ELQV}	Flash	nCE to Output Delay		90	ns
t_{EHQZ}	Flash	nCE High to Output in High Impedance		55	ns

Table 21-43. AC Characteristics for a Write Access



AC Characteristic	Device	Definition	Min	Max	Unit
t_{AVAV}	Flash	Write Cycle Time	90		ns
t_{ELEH}	Flash	nCE Pulse Width Low	50		ns
t_{EHEL}	Flash	nCE Pulse Width High (not shown in Figure 21-33)	30		ns

Figure 21-32. LH28F800BJE-PTTL90 to EMIF Read Timing Waveforms

Copyright © 2018, Texas Instruments Incorporated

Figure 21-33. LH28F800BJE-PTTL90 to EMIF Write Timing Waveforms

The R_STROBE field should be set to meet the following equation:

$R\_STROBE >= (t_D + t_{ELQV} + t_{SU}) \times f_{EMIF\_CLK} - 1$

R_STROBE >= (7 ns + 90 ns + 6.5 ns) × 100 MHz - 1

R_STROBE >= 9.35

R_STROBE = 10

The R_HOLD field must be large enough to satisfy the EMIF Data hold time, t_H:

$R\_HOLD >= t_H \times f_{EMIF\_CLK} - 1$

R_HOLD >= 1 ns × 100 MHz - 1

R_HOLD >= -0.9

The R_HOLD field must also combine with the TA field to satisfy the Flash's nCE High to Output in High Impedance time, t_{EHQZ}:

$R\_HOLD + TA >= (t_D + t_{EHQZ}) \times f_{EMIF\_CLK} - 2$

R_HOLD + TA >= (7 ns + 55 ns) × 100 MHz - 2

R_HOLD + TA >= 4.2

The largest value that can be programmed into the TA field is 3h, therefore the following values can be used:

R_HOLD = 2

TA = 3

For Writes, the W_STROBE field should be set to satisfy the Flash's nCE Pulse Width constraint, t_{ELEH}:

$W\_STROBE >= t_{ELEH} \times f_{EMIF\_CLK} - 1$

W_STROBE >= 50 ns × 100 MHz - 1

W_STROBE >= 4

Copyright © 2018, Texas Instruments Incorporated

The W_SETUP and W_HOLD fields should combine to satisfy the Flash's nCE Pulse Width High constraint, t_{EHEL}, when performing back-to-back writes:

W_SETUP + W_HOLD > = t_{EHEL} × f_{EMIF_CLK} - 2

W_SETUP + W_HOLD > = 30 ns × 100 MHz - 2

W_SETUP + W_HOLD > = 1

In addition, the entire Write access length must satisfy the Flash's minimum Write Cycle Time, t_{AVAV}:

W_SETUP + W_STROBE + W_HOLD >= t_{AVAV} × f_{EMIF_CLK} - 3

W_SETUP + W_STROBE + W_HOLD >= 90 ns × 100 MHz - 3

W_SETUP + W_STROBE + W_HOLD >= 6

Solving the above equations for the Write fields results in the following possible solution:

W_SETUP = 1

W_STROBE = 5

W_HOLD = 0

Adding a 10 ns (1 cycle) margin to each of the periods (excluding TA which is already at its maximum) in this example produces the following recommended values:

W_SETUP = 2h

W_STROBE = 6h

W_HOLD = 1h

R_SETUP = 1h

R_STROBE = Bh

R_HOLD = 3h

TA = 3h

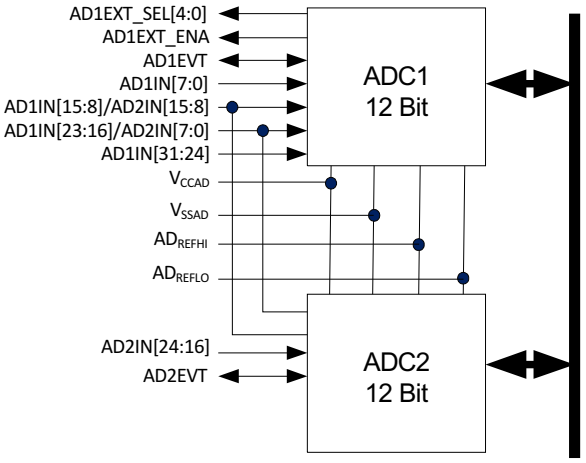
22.1 Overview

This microcontrollers implements up to two instances of the ADC module. The main features of the ADC module are:



- Selectable 10-bit or 12-bit resolution
- Successive-approximation-register architecture
- Three conversion groups – Group1, Group2, and Event Group
- All three conversion groups can be configured to be hardware-triggered; group1 and group2 can also be triggered by software
- Conversion results are stored in a 64-word memory (SRAM)
  - These 64 words are divided between the three conversion groups and are configurable by software
  - Accesses to the conversion result RAM are protected by parity
- Flexible options for generating DMA requests for transferring conversion results
- Selectable channel conversion order
  - Sequential conversions in ascending order of channel number, OR
  - User-defined channel conversion order with the Enhanced Channel Selection Mode
    - The Enhanced Channel Selection Mode is only available to ADC1.
- Single or continuous conversion modes
- Embedded self-test logic for input channel failure detection (open / short to power / short to ground)
- Embedded calibration logic for offset error correction
- Enhanced Power-down mode
- External event pin (ADEVT) to trigger conversions
  - ADEVT is also programmable as general-purpose I/O
- Eight hardware events to trigger conversions

Copyright © 2018, Texas Instruments Incorporated

The two instances of the 12-bit ADC modules on the microcontroller share 16 analog input channels. The connections are shown in Figure 22-1.

- ADC1 supports 32 channels.
- ADC2 supports 25 channels, of which 16 channels are shared with ADC1.
- When using both ADC1 and ADC2 on a shared channel, the sample windows must be identical such that the sample windows completely match each other or non-overlapping with a minimum of 2 ADC cycles buffer between the end of one ADC's sample window and the start of the other ADC's sample window.
- The reference voltages, as well as operating supply and ground, are shared between the two ADC cores.

Figure 22-1. Channel Assignments of Two ADC Cores

22.1.1 Introduction

This section presents a brief functional description of the analog-to-digital converter (ADC) module. Figure 22-2 shows the components of the ADC module.

Figure 22-2. ADC Block Diagram

Copyright © 2018, Texas Instruments Incorporated

22.1.1.1 Input Multiplexor

The input multiplexor (MUX) connects the selected input channel to the AIN input of the ADC core. The ADC1 module supports up to 32 inputs as shown in Figure 22-2. The ADC2 module supports up to 25 inputs. The sequencer selects the channel to be converted. Enabling the enhanced channel selection mode also allows one or more of the analog input channels to be connected to the output of an external analog switch or multiplexor.

22.1.1.2 Self-Test and Calibration Cell

The ADC includes specific hardware that allows a software algorithm to detect open/short on an ADC analog input. It also allows the application program to calibrate the ADC. Also see Section 22.2.6.1 and Section 22.2.6.2.

22.1.1.3 Analog-to-Digital Converter Core

The ADC core is a combination voltage scaling, charge redistribution Successive Approximation Register (SAR) based analog-to-digital converter. The core can be configured for operation in 10-bit resolution (default) or 12-bit resolution. This is controlled by the sequencer logic. This selection applies to all conversions performed by the ADC module. It is not possible to convert some channels with a 12-bit resolution and some with a 10-bit resolution.

A single conversion from an analog input to a digital conversion result occurs in two distinct periods:

- Sampling Period:
  - The sequencer generates a START signal to the ADC core to signal the start of the sampling period.
  - The analog input signal is sampled directly on to the switched capacitor array during this period, providing an inherent sample-and-hold function.
  - The sampling period ends one full ADCLK after the falling edge of the START signal.
  - The sequencer can control the sampling period duration by configuring the conversion group's sample time control register (ADEVSAMP, ADG1SAMP, ADG2SAMP). This register controls the time for which the START signal stays high.
- Conversion Period:
  - The conversion period starts one full ADCLK after the falling edge of START.
  - One bit of the conversion result is output on each rising edge of ADCLK in the conversion period, starting with the most-significant bit first.
  - The conversion period is 12 ADCLK cycles in case of a 12-bit ADC, and is 10 ADCLK cycles in case of a 10-bit ADC.
  - The ADC core generates an End-Of-Conversion (EOC) signal to the sequencer at the end of the conversion period. At this time the complete 12-, or 10-bit conversion result is available.
  - The sequencer captures the ADC core conversion result output as soon as EOC is driven High.

The analog conversion range is determined by the reference voltages: AD_{REFHI} and AD_{REFLO}. AD_{REFHI} is the top reference voltage and is the maximum analog voltage that can be converted. An analog input voltage equal to AD_{REFHI} or higher results in an output code of 0x3FF for 10-bit resolution and 0xFFF for 12-bit resolution. AD_{REFLO} is the bottom reference voltage and is the minimum analog voltage that can be converted. Applying an input voltage equal to AD_{REFLO} or lower results in an output code of 0x000. Both AD_{REFHI} and AD_{REFLO} must be chosen not to exceed the analog power supplies: V_{CCAD} and V_{SSAD}, respectively. Input voltages between AD_{REFHI} and AD_{REFLO} produce a conversion result given by Equation 27 for 10-bit resolution and by Equation 28 for 12-bit resolution.

$$DigitalResult = \frac{1024 \; x \; (InputVoltage - AD_{REFLO})}{AD_{REFHI} - AD_{REFLO}} - 0.5 \quad (27)$$

$$DigitalResult = \frac{4096 \, x (InputVoltage - AD_{REFLO})}{(AD_{REFHI} - AD_{REFLO})} - 0.5 \quad (28)$$

Copyright © 2018, Texas Instruments Incorporated

22.1.1.4 Sequencer

The sequencer coordinates the operations of the ADC, including the input multiplexor, the ADC core, and the result memory. In addition, the logic of the sequencer sets the status register flags when the conversion is ongoing, stopped, or finished.

All the features of the sequencer are discussed in detail in the following sections of this document.

22.1.1.5 Conversion Groups

Several applications require groups of channels to be converted using a single trigger source for example. There could also be some groups of channels identified which require a specific setting of the acquisition time. The ADC module supports three conversion groups for this purpose – Group1, Group2 and the Event Group.

Any of the available analog input channels can be assigned to any of the conversion groups. This also allows a particular channel to be repeatedly sampled by selecting it in multiple groups. There is an inherent priority scheme used when multiple conversion groups are triggered at once. The Event Group is the highest-priority, followed by the Group1 and then the Group2.

The Event Group is always hardware event-triggered. Group1 and Group2 are software-triggered by default and can be configured to be hardware-, or event-triggered as well. The triggering of conversions in each group is discussed in Section 22.2.1.6.

Each conversion group has a separate set of control registers to:

- Select the input channels to be converted
- Configure the mode of conversion: single conversion sequence or continuous conversions
- Configure the input channel sampling time
- Configure the interrupt and/or DMA request generation conditions

22.2 Basic Operation

22.2.1 Basic Features and Usage of the ADC

This section describes the usage of the basic features of the ADC module.

22.2.1.1 How to Select Between 12-bit and 10-bit Resolutions

The 10_12_BIT field of the ADC Operating Mode Control Register (ADOPMODECR) configures the ADC to be in 10-bit or 12-bit resolution mode:

- If 10_12_BIT = 0, the module is in 10-bit resolution mode. This is the default mode of operation.
- If 10_12_BIT = 1, the module is in 12-bit resolution mode.

22.2.1.2 How to Set Up the ADCLK Speed

The ADC sequencer generates the clock for the ADC core, ADCLK. The ADC core uses the ADCLK signal for its timing. The ADCLK is generated by dividing down the input clock to the ADC module, which is the VBUSP interface clock, VCLK. A 5-bit field (PS) in the ADC Clock Control Register (ADCLOCKCR) is used to divide down the VCLK by 1 up to 32. The ADCLK valid frequency range is specified in the device datasheet.

$f_{ADCLK} = f_{VCLK} / (PS + 1)$

The maximum frequency for ADCLK is specified in the device datasheet.

Copyright © 2018, Texas Instruments Incorporated

22.2.1.3 How to Set Up the Input Channel Acquisition Time

The signal acquisition time for each group is separately configurable using the ADG1SAMP[11:0], ADG2SAMP[11:0], and ADEVSAMP[11:0] registers.

The acquisition time is specified in terms of ADCLK cycles and ranges from a minimum of 2 ADCLK cycles to a maximum of 4098 ADCLK cycles.

For example, Group1 acquisition time, t_{ACQG1} = G1SAMP[11:0] + 2, in ADCLK cycles.

The minimum acquisition time is specified in the device datasheet. This time also depends on the impedance of the circuit connected to the analog input channel being converted. See the *ADC Source Impedance for Hercules™ ARM® Safety MCUs Application Report* (SPNA118).

22.2.1.4 How to Select an Input Channel for Conversion

The ADC module needs to be enabled first before selecting an input channel for conversion. The ADC module can be enabled by setting the ADC_EN bit in the ADC Operating Mode Control Register (ADOPMODECR). Multiple input channels can be selected for conversion in each group. Only one input channel is converted at a time. The channels to be converted are configured in one or more of the three conversion groups' channel selection registers. Channels to be converted in Group1 are configured in the Group1 Channel-Select Register (ADG1SEL), those to be converted in Group2 are configured in the Group2 Channel-Select Register (ADG2SEL), and those to be converted in the Event Group are configured in the Event Group Channel-Select Register (ADEVSEL).

The description in this section only refers to the case when the enhanced channel selection mode is not enabled. Input channel selection in the enhanced channel selection mode is defined in Section 22.2.2.

22.2.1.5 How to Select Between Single Conversion Sequence or Continuous Conversions

Each group has its own mode control register. The MODE field of these control registers allow the application to select between a single conversion sequence or continuous conversion mode.

NOTE: Selecting continuous conversion mode for all three groups

All three conversion groups cannot be configured to be in a continuous conversion mode. If the application configures the group mode control registers to enable continuous conversion mode for all three groups, then the Group2 will be automatically be configured to be in a single conversion sequence mode.

With conversions ongoing in continuous conversion mode, if the MODE field of a group is cleared, then that group switches to the single conversion sequence mode. Conversions for this group will stop once all channels selected for that group have been converted.

22.2.1.6 How to Start a Conversion

The conversion groups Group1 and Group2 are software-triggered by default. A conversion in these groups can be started just by writing the desired channels to the respective Channel-Select Registers. For example, in order to convert channels 0, 1, 2, and 3 in Group1 and channels 8, 9, 10, and 11 in Group2, the application just has to write 0x0000000F to ADG1SEL and 0x00000F00 to ADG2SEL. The ADC module will start by servicing the group that was triggered first, Group1 in this example.

The conversions for all groups are performed in ascending order of the channel number. For the Group1 the conversions will be performed in the order: channel 0 first, followed by channel 1, then channel 2, and then channel 3. The Group2 conversions will be performed in the order: channels 8, 9, 10, and 11.

The Event Group is only hardware-triggered. There are up to eight hardware event trigger sources defined for the ADC module. Check the device datasheet for a complete listing of these eight hardware trigger options.

The trigger source to be used needs to be configured in the ADEVSRC register. Similar registers also exist for the Group1 and Group2 as these can also be configured to be event-triggered.

The polarity of the event trigger is also configurable, with a falling edge being the default.

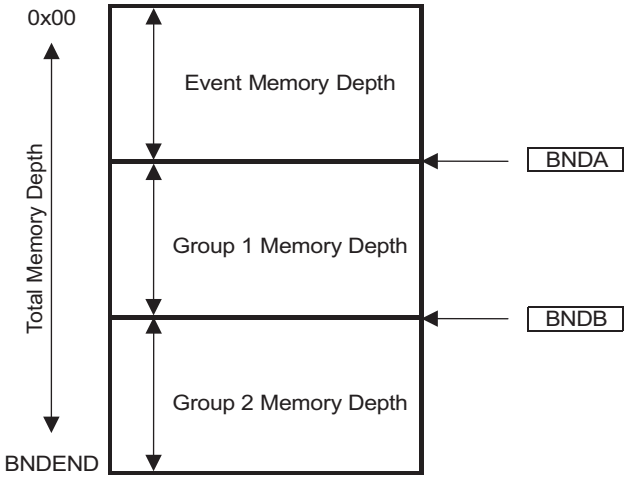
Copyright © 2018, Texas Instruments Incorporated

An Event Group conversion starts when at least one channel is selected for conversion in this group, and when the defined event trigger occurs.

If any conversion group is configured to be in a continuous conversion mode, then it needs to only be triggered once. All the channels selected for conversion in that group will be converted repeatedly.

22.2.1.7 How to Know When the Group Conversion is Completed

Each conversion group has a status flag to indicate when its conversion has ended. See ADEVSR, ADG1SR, and ADG2SR. This bit is set when a conversion sequence for a group ends. This bit does is always set if a group is configured for continuous conversions.



22.2.1.8 How Results are Stored in the Results' Memory

The ADC stores the conversion results in three separate memory regions in the ADC Results' RAM, one region for each group. Each memory region is a stack of buffers, with each buffer capable of holding one conversion result. The number of buffers allocated for each group is programmed by configuring the ADC module registers ADBNDCR and ADBNDEND.

ADBNDCR contains two 9-bit pointers BNDA and BNDB. BNDA, BNDB, and BNDEND are used to partition the total memory available into three memory regions as shown in Figure 22-3. Both BNDA and BNDB are pointers referenced from the start of the results' memory. BNDA specifies the number of buffers allocated for the Event Group conversion results in units of two buffers; BNDB specifies the number of buffers allocated for the Event Group plus Group1 in units of two buffers. Refer to Section 22.3.23 for more details on configuring the ADC results' memory.

ADBNDEND contains a 3-bit field called BNDEND that configures the total memory available. The ADC module can support up to 1024 buffers. The device supports a maximum of 64 buffers for both the ADC modules.

Figure 22-3. FIFO Implementation

- Number of buffers for Event Group = 2 × BNDA
- Number of buffers for Group1 = 2 × (BNDB – BNDA)
- Number of buffers for Group2 = Total number of buffers – 2 × BNDB

22.2.1.9 How to Read the Results from the Results' Memory

The CPU can read the conversion results in one of two ways:

1. By using the conversion results memory as a FIFO queue
2. By accessing the conversion results memory directly

Copyright © 2018, Texas Instruments Incorporated

22.2.1.9.1 Reading Conversion Results from a FIFO

The conversion results for each group can be accessed via a range of addresses provided to facilitate the use of the ARM Cortex-R4 CPU's Load-Multiple (LDM) instruction. A single read performed using the LDR instruction can also be used to read out a single conversion result. The results are read out from the group's memory region as a FIFO queue by reading from any location inside this address range. The conversion result that got stored first gets read first. A result that is read from the memory in this method is removed from the memory. For example, a read from any address in the range ADEVBUFFER (offset 90h to AFh) pulls out one conversion result from the Event Group memory.

Figure 22-4. Format of Conversion Result Read from FIFO, 12-bit ADC

Offset Address Register	31 15	30 14	29 13	28 12	27 11	26 10	25 9	24 8	23 7	22 6	21 5	20 4	19 3	18 2	17 1	16 0
0x90 to 0xAF ADEVBUFFER	EV_ EMPTY	Reserved										EV_CHID				
	Reserved				EV_DR											
0xB0 to 0xCF ADG1BUFFER	G1_ EMPTY	Reserved										G1_CHID				
	Reserved				G1_DR											
0xD0 to 0xEF ADG2BUFFER	G2_ EMPTY	Reserved										G2_CHID				
	Reserved				G2_DR											

Figure 22-5. Format of Conversion Result Read from FIFO, 10-bit ADC

Offset Address Register	31 15	30 14	29 13	28 12	27 11	26 10	25 9	24 8	23 7	22 6	21 5	20 4	19 3	18 2	17 1	16 0
0x90 to 0xAF ADEVBUFFER	Reserved															
	EV_ EMPTY	EV_CHID						EV_DR								
0xB0 to 0xCF ADG1BUFFER	Reserved															
	G1_ EMPTY	G1_CHID						G1_DR								
0xD0 to 0xEF ADG2BUFFER	Reserved															
	G2_ EMPTY	G2_CHID						G2_DR								

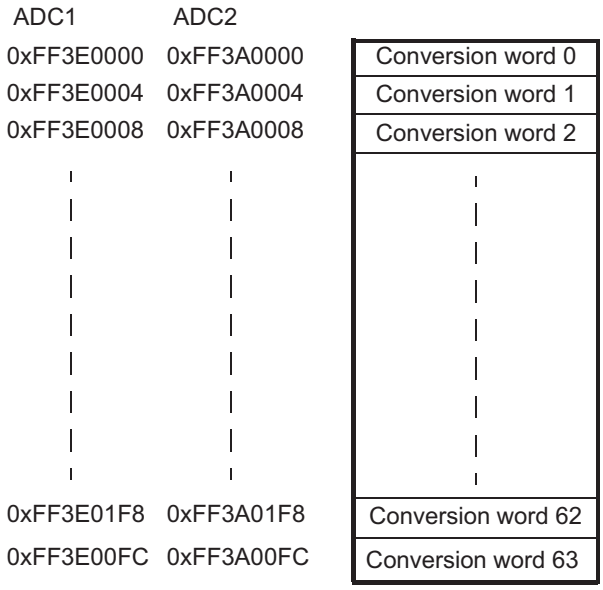
Option to read channel id along with conversion result:

The application has an option to read the channel id along with the conversion result. This is controlled by the CHID field of the group's mode control register. If the option to read the channel id is not selected, the channel id field of the conversion result reads as zeros.

Protection against reading from empty FIFO:

There is also a hardware mechanism to protect the application from reading past the number of new conversion results held in the FIFO. Once all available conversion results have been read out of the FIFO by the application, a subsequent read from the FIFO causes the mechanism to indicate that the FIFO is empty by setting the EMPTY field.

Debug / Emulation Support:



For debug purposes, each conversion group also provides an address that the application can read from for extracting the group's conversion results. However, no status flags for a conversion group are affected by reading from these emulation buffer addresses. For example, reading from ADEVEMUBUFFER (offset F0h) returns the next result in the Event Group buffer but does not actually remove that result from the buffer or change the amount of data held in the buffer.

Copyright © 2018, Texas Instruments Incorporated

22.2.1.9.2 Reading Conversion Results Directly from the Conversion Results' Memory

The conversion result memory is part of the device's memory map. The base address for the ADC1 result memory is FF3E 0000h and for the ADC2 result memory is FF3A 0000h.

Figure 22-6. ADC Memory Mapping

The application can identify the address ranges for each of the three memory regions for the three conversion groups after performing the segmentation as described in Section 22.2.1.8. It is up to the application to read the desired results from the three conversion groups. The formats of the conversion results when reading from RAM directly are shown in Figure 22-7 and Figure 22-8.

Figure 22-7. Format of Conversion Result Directly Read from ADC RAM, 12-bit ADC

	31 15	30 14	29 13	28 12	27 11	26 10	25 9	24 8	23 7	22 6	21 5	20 4	19 3	18 2	17 1	16 0
ADC RAM address	Reserved															channel id [4]
	channel id [3–0]				12-bit conversion result											

Figure 22-8. Format of Conversion Result Directly Read from ADC RAM, 10-bit ADC

	31 15	30 14	29 13	28 12	27 11	26 10	25 9	24 8	23 7	22 6	21 5	20 4	19 3	18 2	17 1	16 0
ADC RAM address	Reserved															
	Rsvd	channel id [4–0]					10-bit conversion result									

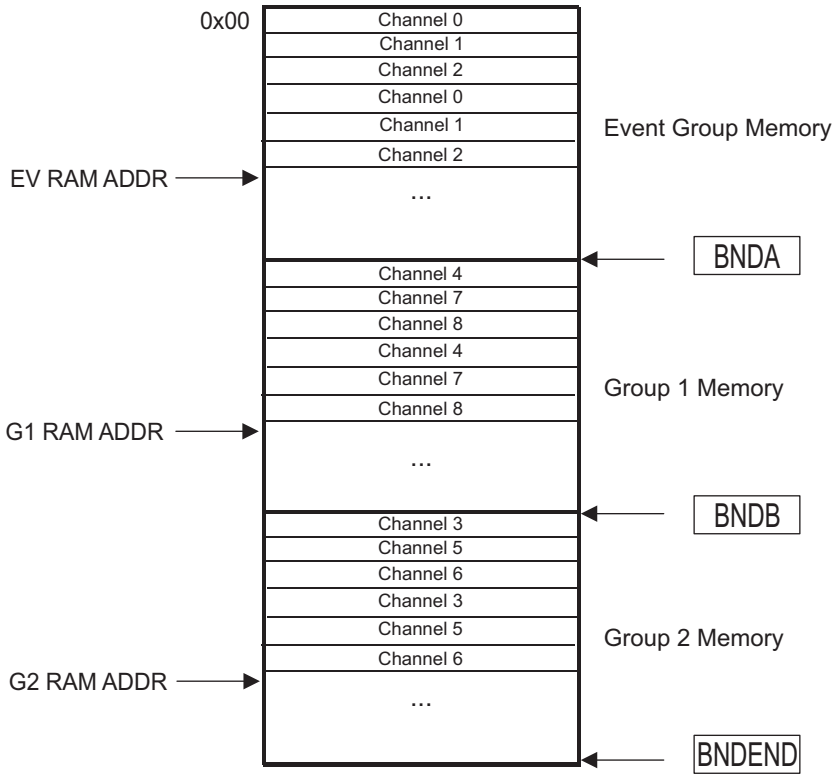
Note that there is no EMPTY field to protect the application from reading data that has been previously read.

Each group does have a separate register which holds the address in the group's result memory where the ADC will write the next conversion result. These are the ADEVRAMWRADDR, ADG1RAMWRADDR, and ADG2RAMWRADDR registers. The application can use this information to calculate how many valid conversion results are available to be read.

Benefit of reading conversion results directly from ADC RAM:

The application does not have to read out conversion results sequentially as in the case of reading from a FIFO. As a result, the application can selectively read the conversion results for any particular input channel of interest without having to read other channels' conversion results.

Copyright © 2018, Texas Instruments Incorporated



22.2.1.9.3 Example

Suppose that channels 0, 1, and 2 are selected for conversion in the Event Group, channels 4, 7, and 8 are selected for conversion in group 1, and channels 3, 5, and 6 are selected for conversion in group 2. The conversion results will get stored in the three memory regions as shown in Figure 22-9.

Suppose that the CPU wants to read out the results for the Event Group from a FIFO queue. The CPU needs to read from any address in the range ADEVBUFFER (offset 90h to AFh) multiple times, or do a "load multiple" from this range of addresses. This will cause the ADC to return the results for channel 0, then channel 1, then channel 2, then channel 0, and so on for each read access to this address range.

Now suppose that the application wants to read out the results for the group 1 from the RAM directly. The conversion results for the group 1 are accessible starting from address ADC RAM Base Address + BNDA. Also, it is known that the first result at this address is for the input channel 4, the next one is for input channel 7, and so on. So the application can selectively read the conversion results for only one channel if so desired.

Figure 22-9. Conversion Results Storage

Copyright © 2018, Texas Instruments Incorporated

22.2.1.10 How to Stop a Conversion

A group's conversion can be stopped by clearing the group's channel select register.

22.2.1.11 Example Sequence for Basic Configuration of ADC Module

The following sequence is necessary to configure the ADC to convert channels 0, 2, 4, and 8 in single-conversion mode using Group1:

1. Write 0 to the Reset Control Register (ADRSTCR) to release the module from the reset state
2. Write 1 to the ADC_EN bit of the Operating Mode Control Register (ADOPMODECR) to enable the ADC state machine
3. Configure the ADCLK frequency by programming the desired divider into the Clock Control Register (ADCLOCKCR)
4. Configure the acquisition time for the group that is to be used. For example, configure the Group1 Sampling Time Control Register (ADG1SAMP) to set the acquisition time for Group1.
5. Select the channels that need to be converted in Group1 by writing to the Group1 Channel Select Register (ADG1SEL). In this example, a value of 0x115 needs to be written to ADG1SEL in order to select channels 0, 2, 4, and 8 for conversion in Group1.
   - The ADC sequencer will start the Group1 conversions as soon as the write to the ADG1SEL register is completed.
6. Wait for the GP1_END bit to be set in the Group1 Conversion Status Register (ADG1SR). This bit gets set when all the channels selected for conversion in Group1 are converted and the results are stored in the Group1 memory.
7. Read the conversion results by reading from the Group1 FIFO access location (ADG1BUFFER) or by reading directly from the Group1 results' memory.

Copyright © 2018, Texas Instruments Incorporated

22.2.2 Advanced Conversion Group Configuration Options

Figure 22-10 shows the operating mode control registers and the status registers for each of the three conversion groups. The register addresses shown are offsets from the base address. The ADC1 register frame base address is FFF7 C000h and the ADC2 register frame base address is FFF7 C200h.

Figure 22-10. ADC Groups' Operating Mode Control and Status Registers

22.2.2.1 Group Trigger Options

The Group1 and Group2 operating mode control registers have an extra control bit: HW_TRIG. This bit configures the group to be hardware event-triggered instead of software-triggered, which is the default.

When a group is configured to be event-triggered, the group conversion starts when at least one channel is selected for conversion in this group, and when the defined event trigger occurs. The event trigger source is defined for each group in the ADEVSRC, ADG1SRC, and the ADG2SRC registers. The actual connections used as the event trigger sources are defined in the device datasheet for both the ADC modules.

22.2.2.2 Analog Input Channel Selection Mode Options

The ADC1 module on this device supports two different modes for selecting the analog input channel to be converted:

- Sequential channel selection mode (default)
- Enhanced channel selection mode

NOTE: ADC2 module only supports the sequential channel selection mode (the default).

22.2.2.2.1 Sequential Channel Selection Mode

This is the default mode and allows the ADC module to be used in a backwards compatible mode to the ADC module on other Hercules™ ARM® Safety MCUs from Texas Instruments. As discussed in Section 22.2.1.4, an analog input channel can be selected for conversion in one or more conversion groups by setting the bit corresponding to that channel number in the group's channel select register.

22.2.2.2.2 Enhanced Channel Selection Mode

There are some important concepts related to the enhanced channel selection mode. These are defined first:

- Look-Up Table

  This is a 32-word deep memory-mapped region used to define the analog input channel number to be converted. The LUTs for the three groups are stacked together so that the entire LUT occupies 96 words. Each word is aligned on a 32-bit boundary. The LUTs for ADC1 start at FF3E 2000h and the LUTs for ADC2 start at FF3A 2000h.
- Conversion Group Sub-Sequence

  A group sub-sequence is defined as the conversion for a set of channels that is converted on each conversion trigger. The number of channels selected for conversion in a group sub-sequence is defined by the number of bits that are set in the group's channel select register. For example, setting bits 0, 1, 29 and 31 in ADG1SEL means that each Group1 conversion sub-sequence consists of 4 conversions.
- LUT Index

  A "CURRENT_COUNT" register for each group is maintained as an index into that group's LUT. This register increments each time a channel conversion is completed. Therefore, as its name suggests, a read from this register returns the number of conversions completed since the last write to the group's channel select register. The CURRENT_COUNT register resets to all zeros under any of the following conditions:

  1. The ADC peripheral is reset via a global peripheral reset
  2. The ADC peripheral is reset via the ADC Reset Control Register
  3. The CURRENT_COUNT becomes equal to the MAX_COUNT defined for that conversion group
  4. The application writes zeros to the CURRENT_COUNT register
  5. The conversion group's result RAM is reset

Copyright © 2018, Texas Instruments Incorporated

- Maximum Number of Conversions

  A MAX_COUNT register for each conversion group stores the maximum number of conversions to be performed before the index into a group's LUT is reset to 0. This register can be programmed to a value between 0 and 31. It is recommended to program the MAX_COUNT register with a value that is one less than a multiple of the number of channels in that group's conversion sub-sequence (number of bits that are set in the group's channel select register).

22.2.2.2.2.1 Look-Up Table Details

As described earlier, each conversion group has a look-up table (LUT) which is used when the enhanced channel selection mode is enabled. This look-up table starts at an offset of 8kB from the base of the ADC results RAM. The LUT holds 32 entries for each of the three conversion groups. The first 32 entries are for the event group, the next 32 entries are for Group1 and the last 32 entries are for Group2. Figure 22-11 shows an example LUT entry for the Event group.

Figure 22-11. Example Look-Up Table Entry

31	16
Reserved	
R-0	

15 13	12 8	7 5	4 0
Reserved	EV_EXT_CHN_MUX_SEL	Reserved	EV_INT_CHN_MUX_SEL
R-0	R/W-0	R-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-1. ADC Look-Up Table Field Descriptions

Bit	Field	Value	Description
31–13	Reserved	0	Reads return 0. Writes have no effect.
12–8	EV_EXT_CHN_MUX_SEL		This field defines the external analog mux select that is output from the ADC module when the Event group CURRENT_COUNT register points to this LUT entry, and when the Event group conversion is triggered with the enhanced channel selection mode enabled.
7–5	Reserved	0	Reads return 0. Writes have no effect.
4–0	EV_INT_CHN_MUX_SEL		This field defines the internal analog mux select that is output from the ADC module when the Event group CURRENT_COUNT register points to this LUT entry, and when the Event group conversion is triggered with the enhanced channel selection mode enabled. This can be a value between 0 and 31, which corresponds to the internal analog input channel number between 0 and 31. Note that this device only supports 24 input channels for ADC1 and 16 input channels for ADC2. If the application configures an unavailable channel number in the EV_INT_CHN_MUX_SEL field, the ADC will still perform the conversion and the result will be indeterminate.

22.2.2.2.2.2 Example ADC Conversion Sequence Using Enhanced Channel Selection Mode

Consider the example conversion Group1 configuration shown in Figure 22-12. Only bits 0 and 31 of ADG1SEL are set. Assume that all other bits in this register are zeros.

In case of the default sequential channel selection mode, the write to the ADG1SEL register would cause the Group1 conversions to start with channel 0 followed by channel 31. The conversions would then stop or repeat in this order depending on whether Group1 is in single or continuous conversion mode.

Figure 22-12. Group1 Enhanced Channel Selection Mode Example

Copyright © 2018, Texas Instruments Incorporated

Now suppose that the application has enabled the enhanced channel selection mode for Group1 with the G1_MAX_COUNT register configured to be 3. Also suppose that the application has programmed the Group1 LUT as shown in Figure 22-12. Now suppose that the application triggers Group1 conversions by writing 0x80000001 to ADG1SEL, that is, bits 0 and 31 are set and all others are zeros. The ADC conversions will proceed in the following sequence:

- Input Channel Selection

  The initial value of G1_CURRENT_COUNT is 0, which is used as the index into the Group1 LUT. The row 0 of Group1's LUT has values of 1 for the G1_EXT_CHN_MUX_SEL and a value of 1 for the G1_INT_CHN_MUX_SEL. The 5-bit external channel id of 0b00001 is driven out on the AD1EXT_SEL terminals. This selects channel 1 for all the connected external analog multiplexors, as shown in Figure 22-12. The ADC module also outputs an enable signal to the external analog multiplexors via the AD1EXT_ENA terminal.

  Now consider the fact that the internal channel id is also configured to be 1 in row 0 of the Group1 LUT. This causes the switch for ADC's internal channel 1 (ADIN1) to be closed. All other internal ADC input switches (ADIN0, ADIN2, ADIN3, ..., ADIN31) will be open. Note that the ADIN1 input channel is actually connected to the output of an 8:1 analog multiplexor.

  In effect, the ADC will convert channel 1 of the 8:1 analog multiplexor connected to the ADIN1 terminal of the microcontroller.

- After Completion of Conversion

  Once the first conversion is completed, the CURRENT_COUNT value of 0 is stored in the "channel id" field of the conversion result RAM of Group1 along with the actual conversion result from the ADC core. Then the G1_CURRENT_COUNT value of 0 is compared against the G1_MAX_COUNT value of 3. The values do not match, so that G1_CURRENT_COUNT is incremented from 0 to 1.

- Next Channel Selection

  There are two bits set in the ADG1SEL register, so that the ADC module now uses the G1_CURRENT_COUNT value of 1 to index the Group1 LUT. As shown in Figure 22-12, this row in Group1 LUT contains 4 as the G1_EXT_CHN_MUX_SEL and 2 as the G1_INT_CHN_MUX_SEL.

  ADC input channel ADIN2 is not connected to any external analog multiplexor and is connected directly to the analog signal to be converted. Note that the ADC module still drives the AD1EXT_ENA and the AD1EXT_SEL (value of 4, that is, 0b00100) to all the external analog multiplexors connected to the microcontroller.

- End of Conversion Sub-Sequence

  Once the conversion of the internal channel ADIN2 is completed, the G1_CURRENT_COUNT of 1 is stored in the "channel id" field of the Group1 result RAM along with the actual conversion result. This value of 1 is compared against the G1_MAX_COUNT value of 3. The values do not match, so that G1_CURRENT_COUNT is incremented from 1 to 2.

  There are no more conversions required in this sub-sequence as only two bits are set in ADG1SEL.

- Continuation on Next Group1 Trigger

  When the ADC Group1 is triggered again or if Group1 is in continuous conversion mode, the G1_CURRENT_COUNT of 2 is again used to index the Group1 LUT. Following the same reasoning as before, this will cause the channel 1 of the 8:1 analog multiplexor connected to ADIN1 to be converted.

  Once this conversion is done, the G1_CURRENT_COUNT value of 2 is stored in the "channel id" field of the result RAM along with the conversion result. This still does not match the G1_MAX_COUNT of 3, so that G1_CURRENT_COUNT is now incremented from 2 to 3.

  This index value of 3 is used to again convert channel ADIN2, following the same reasoning as before.

  When this conversion is completed, the G1_CURRENT_COUNT of 3 is stored as the "channel id" field of the result RAM along with the conversion result.

  Also, now this G1_CURRENT_COUNT value of 3 matches the G1_MAX_COUNT. This resets the G1_CURRENT_COUNT to 0.

The sequence proceeds as described whenever Group1 is next triggered, or if Group1 is configured to be in a continuous conversion mode.

Copyright © 2018, Texas Instruments Incorporated

22.2.2.3 Single or Continuous Conversion Modes

The EV_MODE, G1_MODE, and G2_MODE bits are used to select between either single or continuous conversion mode for each of the three groups.

22.2.2.3.1 Single Conversion Mode

A conversion group configured to be in single-conversion mode gets serviced only once by the ADC for each group trigger. The trigger can be a software trigger as in the case of Group1 and Group2 by default, or it could be a hardware event trigger as in the case of the Event Group or Group1 or Group2.

The entire conversion sequence, from the acceptance of the group conversion request to the end of the last channel's conversion, is flagged for each group by the corresponding BUSY bit in that group's status register. After single-conversion mode is started, the BUSY bit is read as 1 until the conversion of the last channel is complete. The END bit for the group is set once all the channels in that group are converted.

For example, say channels 0, 2, 4, and 6 are selected for conversion in Group1 in single-conversion mode. When the Group1 gets serviced, the ADC will start conversion for channel 0, then channel 2, then channel 4, and then channel 6. It will then stop servicing the Group1, set the GP1_END status bit, and look to service the Event Group or the Group2, if required.

22.2.2.3.2 Continuous Conversion Mode

A conversion group configured to be in continuous-conversion mode gets serviced by the ADC continuously. The group still needs to be triggered appropriately for the first conversion to start. The conversions are performed continuously thereafter.

The entire conversion sequence, from the acceptance of the group conversion request to the end of the last channel's conversion, is flagged for each group by the corresponding BUSY bit in that group's status register. After continuous-conversion mode is started, the BUSY bit is read as 1 as long as the continuous-conversion mode for this group is selected.

As an example, say the channels 0, 2, 4, and 6 are selected for conversion in Group1, now in continuous-conversion mode. When the Group1 gets serviced, the ADC will complete conversions for channels 0, 2, 4 and 6, and then look to service the Event Group or the Group2. Once it is done servicing the Event Group or the Group2, it will return to service the Group1 again. The Group1 does not need to be triggered again for the repeated conversion.

NOTE: Configuring all conversion groups in continuous conversion mode

All the three groups cannot operate in continuous-conversion mode at the same time. If the application program configures all three groups to be in continuous-conversion mode, the Group2 is automatically reset to single-conversion mode, and the G2 MODE bit in the ADG2MODECR register is cleared to reflect the single-conversion mode of Group2.

22.2.2.4 Conversion Group Freeze Capability

The ADC module has an inherent priority order between the three conversion groups. This group priority determines the order of conversion in case multiple groups are triggered. The priority of conversions between the three groups in descending order is:

1. Event Group
2. Group1
3. Group2

Copyright © 2018, Texas Instruments Incorporated

Examples of conversion group priority:

- If an Event Group conversion is ongoing in single conversion sequence mode and Group2 and Group1 conversions are requested, then the ADC will finish conversion of channels selected in Event Group, then switch over to converting channels selected in Group1, and then convert channels selected in Group2.
- If Group1 conversions are ongoing in continuous conversion mode and Group2 conversion is requested, then the ADC will complete converting the current channel for Group1 and switch over to converting channels selected in Group2. The new conversion request for Group2 has a higher priority than the pending continuous conversion request for Group1.

The conversion group freeze capability allows the application to override this default priority between the conversion groups. Enabling the freeze capability allows the ADC to freeze a higher-priority conversion group's conversions whenever there is a request for conversion in another (lower-priority) group.

For example, setting the FRZ_EV bit in the ADEVMODECR register will allow the ADC to freeze ongoing Event Group conversions whenever there is a pending request, or a new request for a Group1 or Group2 conversion. The conversions for the Event Group will be frozen as long as the Group1 or Group2 conversions are active. Once the Group1 or Group2 conversions are completed, the Event Group conversions start from where they were frozen.

While a group's conversions are frozen, the group's STOP status bit is set. This bit is cleared once the group's conversions are restarted.

22.2.2.5 Conversion Group Memory Overrun Option

An overrun condition occurs when the ADC module tries to store more conversion results to a group's results' memory which is already full. In this case, the ADC allows two options.

If the OVR_RAM_IGN bit in the group's operating mode control register (ADEVMODECR, ADG1MODECR, ADG2MODECR) is set, then the ADC module ignores the contents of the group's results' memory and wraps around to overwrite the memory with the results of new conversions.

If the OVR_RAM_IGN bit is not set, then the application program has to read out the group's results' memory upon an overrun condition; only then can the ADC continue to write new results to the memory.

22.2.2.6 Response on Writing Non-Zero Value to Conversion Group's Channel Select Register

If the application writes a non-zero value to a group's channel select register while that group's conversions are already being serviced, then that group's conversions will be restarted with the new configuration programmed in the channel select registers.

The following rules apply in terms of the effect on the ADC conversion sequence:

- If the new conversion request comes from the same group as the ongoing conversion, then the ongoing conversion will be stopped in whichever stage it is in, and the new sequence of conversions will be started.
- If the new conversion request comes from a separate group, then the ongoing channel's conversion will be completed before starting the new sequence of conversions.

The following rules apply in terms of the effect on the group's results memory:

- If a group conversion is ongoing or is frozen, writing a non-zero value to the group's channel select register will also reset its results FIFO. This does not clear the contents of the results FIFO; only the ADC module is allowed to overwrite the FIFO's contents with new conversion results starting from the first location.
- If the group conversion is completed (<GRP>_END flag is set), or the group is not being used, then writing a non-zero value to the group's channel select register will either be reset or not depending on the value of the NoResetOnChnSel bit for that group (ADEVMODECR, ADG1MODECR, ADG2MODECR).
  - If the NoResetOnChnSel bit is 0, then the group's FIFO will be reset.
  - If the NoResetOnChnSel bit is 1, then the group's FIFO will not be reset.

Copyright © 2018, Texas Instruments Incorporated

22.2.2.7 Conversion Result Size on Reading: 8-bit, 10-bit, or 12-bit

Some applications do not need the full 12-bit resolution of the ADC modules on the device and can work with 8-bit or 10-bit conversion results.

22.2.2.7.1 ADC Configured in 12-bit Resolution

The mode control register for each conversion group contains a field called DATA_FMT, which defines the format of the conversion result read out of the result RAM, when accessed as a FIFO.

The DATA_FMT field is encoded as follows:

- If DATA_FMT = 0, the complete 12-bit conversion result is read out of the FIFO.
- If DATA_FMT = 1h, the 12-bit conversion result is right-shifted by 2 and the resulting 10-bit result is read out of the FIFO.
- If DATA_FMT = 2h, the 12-bit conversion result is right-shifted by 4 and the resulting 8-bit result is read out of the FIFO.

This control field is not effective when the application chooses to access the conversion result memory directly. In that case, the application can choose to mask off the number of bits as required.

22.2.2.7.2 ADC Configured in 10-bit Resolution

The DATA_FMT field is not effective in this mode and the application has the choice to read either the full 10-bit conversion result or an 8-bit conversion result. This is controlled by the 8BIT field of the group's operating mode control register.

- If 8BIT = 0, the complete 10-bit conversion result is read out of the FIFO.
- If 8BIT = 1, the 10-bit conversion result is right-shifted by 2 and the resulting 8-bit result is read out of the FIFO.

22.2.2.8 Option to Read Group Channel ID Along With Conversion Result

The ADC module allows the application program to also read out the analog input channel number along with its conversion result. This capability is enabled by setting the CHID bit in the group's operating mode control register.

- If CHID = 0, bits [14-10] are forced to 00000 when the conversion results are read out from the group's results' FIFO.
- If CHID = 1, bits [14-10] in the group's results' memory contain the input channel number to which the conversion result belongs.

NOTE: Actual Storage of Channel ID

Regardless of whether the CHID bit is set or not, the channel number is **always stored** in the memory along with the conversion result. The CHID bit only affects whether the channel number is available with the conversion result **when the group's memory is read**. Therefore, the CHID bit for a group can be changed dynamically without affecting that group's ongoing conversions.

Copyright © 2018, Texas Instruments Incorporated

22.2.3 ADC Module Basic Interrupts

This section describes the basic interrupts generated by the ADC module.

22.2.3.1 Group Conversion End Interrupt

The ADC module sets the group's conversion end flag (EV_END, G1_END, or G2_END) in that group's interrupt flag register (ADEVINTFLG, ADG1INTFLG, ADG2INTFLG) when all the channels selected for conversion in that group are converted. This causes a group conversion end interrupt to be generated if this interrupt is enabled by setting the group's END_INT_EN control bit (EV_END_INT_EN, G1_END_INT_EN, or G2_END_INT_EN).

This interrupt can be easily used for conversion groups configured to be in the single-conversion mode. The application program can read out the conversion results, change the group's configuration if necessary, and restart the conversions by triggering the group from within the interrupt service routine.

For groups configured to be in continuous conversion mode, this interrupt condition is not practical as the conversions are always in progress. In this case, the Group Memory Threshold Interrupt is more practical as the application can allow a programmable number of conversion results to accumulate before interrupting the CPU.

22.2.3.2 Group Memory Threshold Interrupt

The ADC module has the ability to generate an interrupt for a fixed number of conversions for each group. A group memory threshold register determines how many conversion results must be in a group's memory region before the CPU is interrupted. This feature can be used to significantly reduce the CPU load when using interrupts for reading the conversion results.

The group's threshold register needs to be configured before the group conversions are triggered. This threshold register value behaves like a down-counter, which decrements each time the ADC writes a conversion result to this group's memory. This counter is incremented each time the application program reads a conversion result from the results' memory by accessing the FIFO queue. Simultaneous read (by application program) and write (by ADC module) operations from the group's results' memory leave the threshold counter unchanged.

The threshold counter can decrement past 0 and become negative. It always increments back to its original value when the memory region is emptied. To determine how many samples are in the memory region at a given moment, the threshold counter can be subtracted from the originally configured threshold count.

Whenever the threshold counter transitions from +1 to 0, it sets the group's threshold interrupt flag, and the CPU is interrupted if the group's threshold interrupt is enabled. The CPU is expected to clear the interrupt flag after reading the conversion results from the memory.

The interrupt flag is not set when the threshold counter stays at 0 or transitions from -1 to 0.

22.2.3.3 Group Memory Overrun Interrupt

An interrupt can be generated for each group if the number of ADC conversions for that group exceed the number of buffers allocated for that conversion group. The application program can choose to read out all the conversion results using the CPU or the DMA. Alternatively, the application program can set the group's OVR_RAM_IGN bit and allow the ADC module to overwrite the group's results' memory contents with new conversion results.

Copyright © 2018, Texas Instruments Incorporated

22.2.4 ADC Module DMA Requests

This section describes the capabilities of the ADC module to take advantage of the Platform DMA controller module. The ADC module can generate a DMA request under two conditions:

22.2.4.1 DMA Request for Each Conversion Result Written to the Results' Memory

In this mode, the ADC module will generate the first DMA request as soon as a conversion result gets written to the group's results' memory. Subsequent writes to the results' memory will cause DMA requests to be generated. This mode allows a smaller amount of ADC results' memory to suffice for an application.

This DMA request generation is enabled by setting the group's DMA_EN bit in the group's DMA control register. The BLK_XFER bit in this register must be left cleared (default), if a DMA request is desired to be generated for new results getting written to the results' memory.

22.2.4.2 DMA Request for a Fixed Number of Conversion Results

This mode is enabled by setting both the group's DMA_EN and the group's BLK_XFER bits in the group's DMA control registers.

In this mode, a DMA request will be generated for a specified number of conversion results being available in the group's results' memory. The number of conversion results desired are configured using the group's BLOCKS field in the control registers.

For example, if the BLOCK count is configured for 10, then ADC module will generate a DMA request at the end of 10th conversion. DMA controller should complete reading out 10 data before next set of 10 conversions complete.

NOTE: Usage of Block DMA transfers with Threshold Interrupts

It is not recommended to enable the block DMA transfers for a group at the same time as the group threshold interrupt. The group's BLOCKS field is essentially the same as the group's THRESHOLD field in the group's interrupt control register described in Section 22.2.3.2.

Copyright © 2018, Texas Instruments Incorporated

22.2.5 ADC Magnitude Threshold Interrupts

The ADC allows up to three magnitude threshold interrupts to be generated. The comparison parameters are programmed via the Magnitude Threshold Control Register (ADMAGINTxCR).

22.2.5.1 Magnitude Threshold Interrupt Configuration

The following fields are configurable for each of the three available magnitude threshold interrupts:

1. CHN_THR_COMP: Specifies whether to compare two channels' conversion results, or to compare a channel's conversion result to a programmable threshold value. A value of 0 will select the programmable threshold to be compared, and a value of 1 will select the conversion result of the channel identified by the COMP_CHID field to be compared.
2. MAG_CHID: Specifies the channel number from 0 to 31 whose conversion result needs to be monitored.
3. COMP_CHID: Specifies the channel number from 0 to 31 whose last conversion result is used for the comparison with the conversion result of the channel being monitored.
4. MAG_THRESHOLD: Specifies the value for comparison with the conversion result of the channel identified by the MAG_CHID field.
5. CMP_GE_LT: Specifies whether the conversion result of the channel identified by MAG_CHID is compared to be "greater than or equal to", or "less than" the reference value. The reference value can be the conversion result of another channel identified by the COMP CHID field, or it could be a threshold value specified in the MAG_THRESHOLD field. A value of 0 in the CMP_GE_LT field indicates a "less than" comparison and a value of 1 indicates a "greater than or equal to" comparison.

22.2.5.2 Magnitude Threshold Interrupt Comparison Mask Configuration

There is also a separate comparison mask register (ADMAGINTxMASK) for each of the three magnitude threshold interrupts. This register is used to specify the bits that are masked off for the sake of the comparison. For example, the lower 4 bits of the conversion result can be masked off by writing 0xf to the interrupt comparison mask register, allowing a gross comparison to be made. By default, the full 10/12-bit conversion results are compared.

22.2.5.3 Magnitude Threshold Interrupt Enable / Disable Control

Each of the three magnitude interrupts also have separate interrupt enable set (ADMAGINTENASET) and clear (ADMAGINTENACLR) registers. These are used to respectively enable and disable that particular magnitude threshold interrupt from being generated. To enable a magnitude threshold interrupt, write a 1 to the corresponding bit of the interrupt enable set register. Conversely, to disable a magnitude threshold interrupt, write a 1 to the corresponding bit of the interrupt enable clear register.

22.2.5.4 Magnitude Threshold Interrupt Flags

There is a separate Magnitude Interrupt Flag register (ADMAGINTFLG) that holds the flags for these three interrupts. This flag gets set whenever the comparison condition for the corresponding interrupt is met. A magnitude threshold interrupt is generated if the corresponding flag is set inside the flag register, and the interrupt generation is enabled. This flag can be cleared by writing a 1 to the flag or by reading from the interrupt offset register in case of this interrupt being the current highest-priority pending interrupt.

22.2.5.5 Magnitude Threshold Interrupt Offset Register

It is possible to have multiple magnitude threshold interrupts pending at the same time. The magnitude threshold interrupt offset register (ADMAGINTOFF) holds the index of the currently pending highest priority magnitude threshold interrupt. The magnitude threshold interrupt 1 has the highest priority while the magnitude threshold interrupt 3 has the lowest priority. This is a read-only register and returns zeros if none of the magnitude threshold interrupts are pending. Writes to this register have no effect.

A read from this register updates the register to the next highest-priority pending magnitude threshold interrupt. This read also clears the corresponding flag from the magnitude threshold interrupt flag register. However, a read from the magnitude threshold interrupt offset register in emulation mode does not affect the interrupt flag register or the interrupt offset register.

Copyright © 2018, Texas Instruments Incorporated

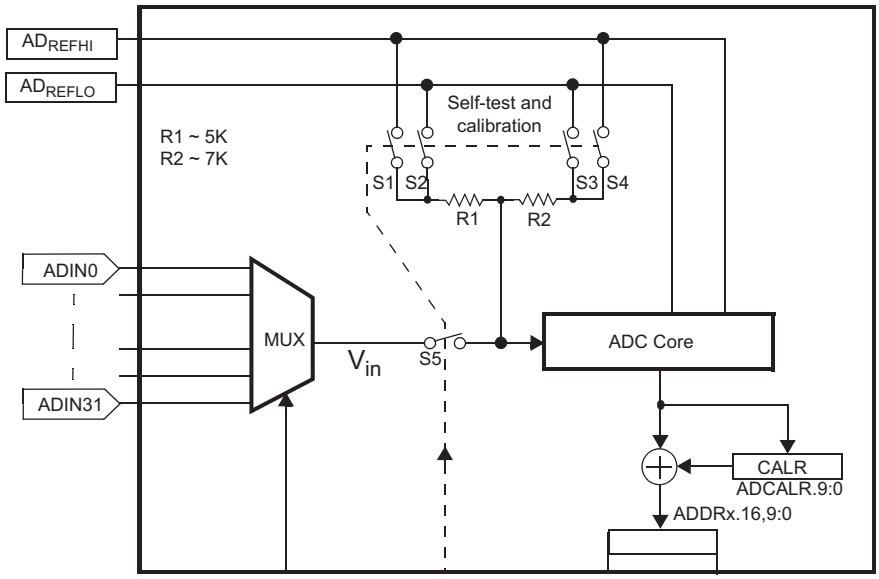
22.2.6 ADC Special Modes

The ADC module supports some special modes for diagnostics and power saving purposes.

22.2.6.1 ADC Error Calibration Mode

The application program can activate a calibration sequence any time self-test mode is disabled (SELF_TEST = 0). This calibration sequence includes the conversion of an embedded calibration reference voltage followed by the calculation of an offset error correction value.

NOTE: Disable Self-Test Mode Before Calibration



To avoid errors during the calibration operation, self-test mode must *not* be enabled during a calibration sequence. In addition, to ensure accurate results, calibrate the ADC in an environment with minimum noise.

Calibration mode is enabled by setting the CAL_EN bit (ADCALCR.0). The application needs to ensure that no conversion group is being serviced when the calibration mode is enabled.

The input multiplexor gets disabled and only the reference voltage is connected to the ADC core input. Switch S5 of Figure 22-13 is opened. In addition, the digital result issued from a conversion is output from the ADC core to the calibration and offset error correction register, ADCALR. The ADC results' memory is not affected by the calibration conversion.

When calibration mode is disabled, the ADC can be configured for normal conversions.

Figure 22-13. Self-Test and Calibration Logic

22.2.6.1.1 Calibration Conversion

The calibration conversion also needs to meet the minimum sampling time specification for the ADC. This value is typically 1 us. The Event Group sample time register (ADEVSAMP) is used to specify the number of ADCLK cycles for the calibration conversion.

The BRIDGE_EN and HILO bits (ADCALCR.9:8) control the voltage to the calibration reference device shown in Figure 22-15. The positions of the switches in calibration mode are listed in Table 22-2.

Copyright © 2018, Texas Instruments Incorporated

Table 22-2. Calibration Reference Voltages[1]

CAL_EN	BRIDGE_EN	HILO	S1	S2	S3	S4	S5	Reference Voltage
1	0	0	1	0	1	0	0	$(AD_{REFHI} \times R1 + AD_{REFLO} \times R2) / (R1 + R2)$
1	0	1	0	1	0	1	0	$(AD_{REFLO} \times R1 + AD_{REFHI} \times R2) / (R1 + R2)$
1	1	0	0	1	1	0	0	AD_{REFLO}
1	1	1	1	0	0	1	0	AD_{REFHI}
0	X	X	0	0	0	0	1	V_{in}

(1) The state of the switches in this table assumes that self-test mode is not enabled.

When CAL_ST (ADCALCR.16) is set, a calibration conversion is started. The voltage source selected via the bits BRIDGE_EN and HILO is converted once (single conversion mode) and the digital result is returned to the calibration and correction register, ADCALR, where it can be read by the CPU. The CAL_ST bit acts as a flag and must be polled by the CPU. It is held set during the conversion process and automatically clears to indicate the end of the reference voltage conversion.

NOTE: No Interrupt for end of calibration

The ADC does not generate an interrupt to signal the end of the calibration conversion. The application must poll the CAL_ST bit to determine the end of the calibration conversion.

After the CAL_ST bit is set by the application program, it can only be reset by the end of the ongoing conversion generated by the ADC core. If the calibration conversion is interrupted (CAL_EN bit is cleared), the CAL_ST bit is held at 1 until a new calibration conversion has been set and completed. Setting the CAL_ST bit while calibration is disabled (CAL_EN = 0) has no effect; however, in this situation, setting CAL_EN immediately starts a calibration conversion. When the calibration conversion is interrupted by an ADC_Enable (ADC_EN = 0, CAL_EN = 1, and CAL_ST = 1), a new conversion is automatically restarted as soon as the ADC_Enable bit is released (ADC_EN = 1).

22.2.6.1.2 Calibration and Offset Error Correction Sequences

The number of measurements and the source to measure for an ADC calibration are application dependent. The CAL_ST bit must be set for each calibration source to be measured. While calibration mode is enabled, any available calibration sources can be converted according to the BRIDGE_EN and HILO bits (see Table 22-2). The digital results of the calibration measurements should be read from ADCALR by the application after each reference conversion so that a correction value can be computed and written back into ADCALR.

When the application has the necessary calibration data, it should compute the offset error correction value and load it into the calibration and correction register, ADCALR. After the CAL_EN bit is cleared, normal conversion mode restarts, continuing from where it was frozen, but with the addition of self-correction data.

In normal mode, the self-correction system adds the correction value stored in ADCALR to each digital result before it is written to the respective group's FIFO.

The basic calibration routine is as follows:

1. Enable calibration via CAL_EN (ADCALCR.0).
2. Select the voltage source via BRIDGE_EN and HILO (ADCALCR.9:8).
3. Start the conversion with CAL_ST (ADCALCR.16).
4. Wait for CAL_ST to go to 0.
5. Get the results from ADCALR and save to memory.
6. Loop to step 2 until the calibration conversion data is collected for the desired reference voltages.
7. Compute the error correction value using calibration data saved in memory.
8. Load the ADCALR register with the 2s complement of the computed error correction value.
9. Disable calibration mode.

Copyright © 2018, Texas Instruments Incorporated

At this point, the ADC can be configured for normal operation, and it corrects each digital result with the error correction value loaded in ADCALR.

NOTE: Prevent ADC Calibration Data From Being Overwritten

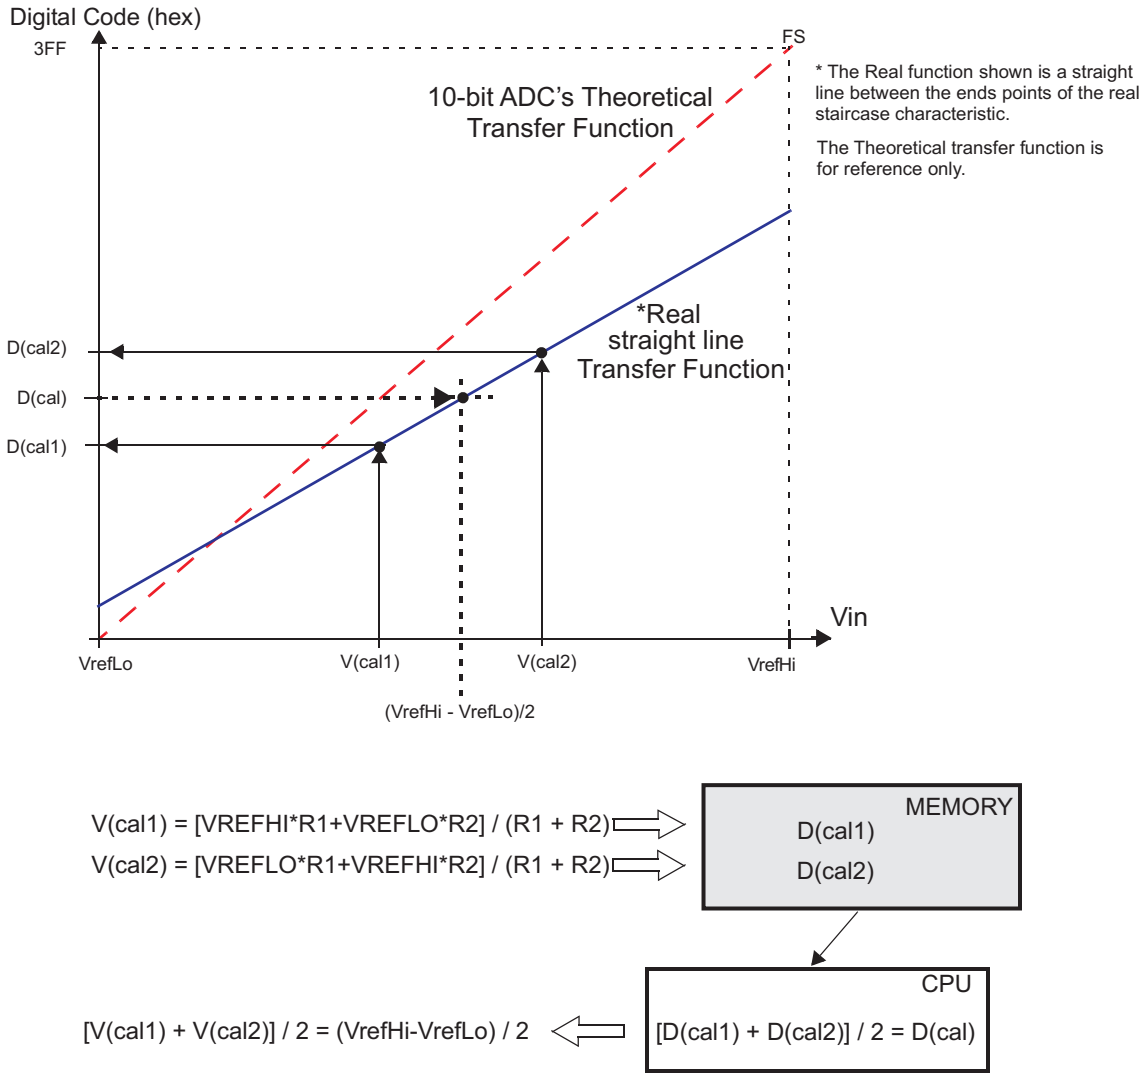
In calibration mode, the conversion result is written to ADCALR that overwrites any previous calibration data; therefore, the ADCALR register must be read before a new conversion is started.

For no correction, a value of 0x0000 must be written to ADCALR. In noncalibration mode, the ADCALR register can be read and written. Any value written to ADCALR in normal mode (CAL_EN = 0) is added to each digital result from the ADC core.

22.2.6.1.3 Mid-Point Calibration

Because of its connections to the ADC's reference voltage (VrefHi, VrefLo), the precision of the calibration reference is voltage independent. On the other hand, the accuracy of the switched bridge resistor (R1 & R2) relies on the manufacturing process deviation. Consequently, the mid-point voltage's accuracy can be affected due to the imperfections in the two resistors (expected mismatch error is around 1.5%).

The switched reference voltage device has been specially designed to support a differential measurement of its mid-point voltage. This ensures the accuracy of the mid-point reference, and hence the efficiency of the calibration.



The differential mid-point calibration is software controlled; the algorithm (voltage source measurements and associated calculation) is inserted within the calibration software module included in the application program.

The basic differential mid-point calibration flow is illustrated here after:

1. The application program connects the voltage VrefHi to R1 and VrefLo to R2, (BRIDGE_EN = 0, HILO = 0), launches a conversion of the input voltage V(cal1), and stores the digital result D(cal1) into the memory.
2. Then the application program switches the voltage VrefHi to R2 and VrefLo to R1 (BRIDGE_EN = 0, HILO = 1), converts this new input voltage V(cal2) and again stores the issued digital result D(cal2) into the memory.
3. The actual value of the real middle point is obtained by computing the average of these two results. [D(cal1)+D(cal2)] /2; Figure 22-14 summarizes the mid-point calibration flow.

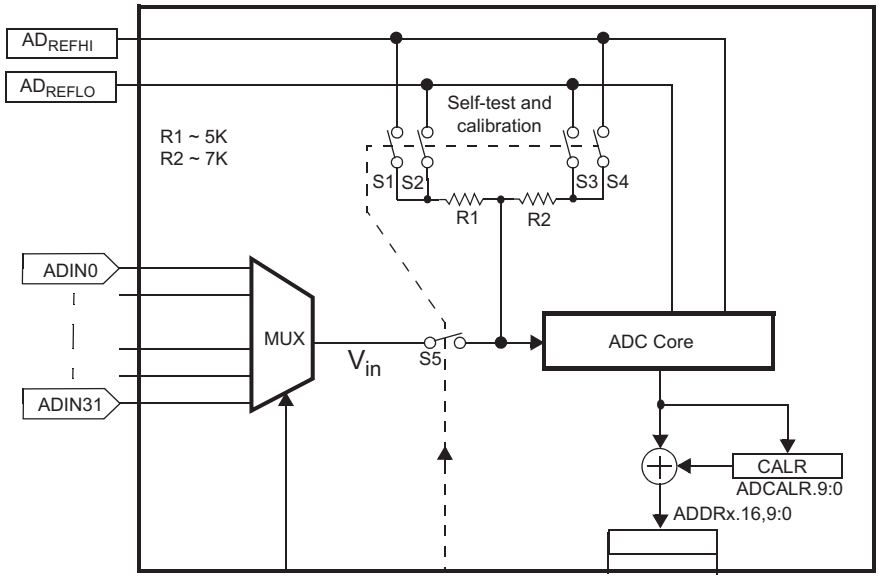
Figure 22-14. Mid-point Value Calculation



22.2.6.2 ADC Self-Test Mode

The ADC module supports a self-test mode which can be used to detect an open or a short on the ADC input channels. Self-test mode is enabled by setting the SELF_TEST bit (ADCALCR.24). Any conversion type (continuous or single conversion, freeze enabled or non-freeze enabled, interrupts enabled or disabled) can be performed in this mode.

In normal mode, setting the self-test mode while a conversion sequence is in process can corrupt the current channel conversion results. However, the next channel in the sequence is converted correctly during the additional self-test cycle. The logic associated with both self-test and calibration is shown in Figure 22-15.

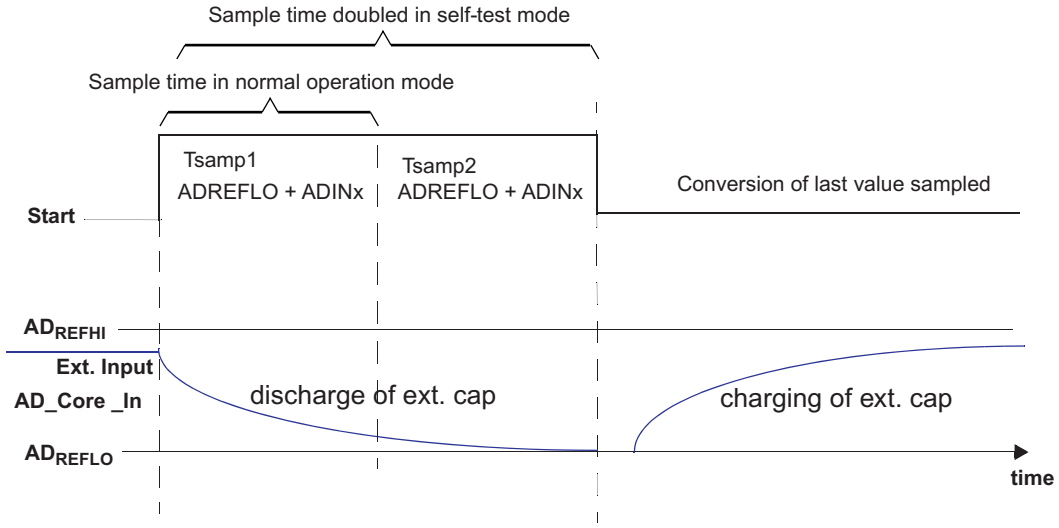
Copyright © 2018, Texas Instruments Incorporated

Figure 22-15. Self-Test and Calibration Logic

In self-test mode, a test voltage defined by the HILO bit (ADCALCR.8) is provided to the ADC core input through a resistor (see Table 22-3). To change the test source, this bit can be toggled before any single conversion mode request. Changing this bit while a conversion is in progress *can* corrupt the results if the source switches during the acquisition period.

Note that the switch S5 shown in Figure 22-15 is only for the purpose of explaining the self-test sequence. There is no physical switch.

Table 22-3. Self-Test Reference Voltages(1)



SELF_TEST	HILO	S1	S2	S3	S4	S5	Reference Voltage
1	0	0	1	1	0	1	AD_{REFLO} via R1 || R2 connected to V_{in}
1	1	1	0	0	1	1	AD_{REFHI} via R1 || R2 connected to V_{in}
0	X	0	0	0	0	1	V_{in}

(1) Switches refer to Figure 22-15.

Conversions in self-test mode are started just as they are in the normal operating mode (see Section 22.2.1.6). The conversion starts according to the configuration set in the three mode control registers (ADEVMODECR, ADG1MODECR, ADG2MODECR) and the sampling time control registers (ADEVSAMP, ADG1SAMP, ADG2SAMP). The acquisition time for each conversion in self-test mode is extended to twice the normal configured acquisition time. The selected reference voltage and the input voltage from the ADINx input channel are both connected to the ADC internal sampling capacitor throughout this extended acquisition period. Figure 22-16 shows the self-test mode timing when the ADREFLO is chosen as the reference voltage for the self-test mode conversion. It also assumes an external capacitor connected to the ADC input channel.

Figure 22-16. Timing for Self-Test Mode

22.2.6.2.1 *Use of Self-Test Mode to Determine Open/Short on ADC Input Channels*

The following sequence needs to be used to deduce the ADC pin status:

- Convert the channel with self test enabled and with the reference voltage as Vreflo. Store the conversion result, say Vd.
- Convert the channel with self test enabled and with the reference voltage as Vrefhi. Store the conversion result, say Vu.
- Convert the channel with self test disabled. Store the conversion result, say Vn.

The results can be interpreted using the following table.

Table 22-4. Determination of ADC Input Channel Condition

Normal Conversion Result, Vn	Self-test Conversion Result, Vu	Self-test Conversion Result, Vd	Pin Condition
Vn	$Vn < Vu < AD_{REFHI}$	$AD_{REFLO} < Vd < Vn$	Good
AD_{REFHI}	AD_{REFHI}	approx. AD_{REFHI}	Shorted to AD_{REFHI}
AD_{REFLO}	approx. AD_{REFLO}	AD_{REFLO}	Shorted to AD_{REFLO}
Unknown	AD_{REFHI}	AD_{REFLO}	Open

22.2.6.3 ADC Power-Down Mode

This is an inactive mode in which the clocks to the ADC module are stopped leaving the module in a static state. The clock to the ADC core (ADCLK) is stopped whenever there are no ongoing conversions. This is the clock-gating implementation requirement. Also, the ADC module places the ADC core into the power down mode such that there is minimal current drawn from the ADC operating and reference supplies.

22.2.6.3.1 *Powering Down Just The ADC Core*

The ADC core can be individually powered down without stopping the clocks to the ADC module. This can be done by setting the POWERDOWN bit of the ADC Operating Mode Control Register (ADOPMODECR.3). Whenever a conversion is required the POWERDOWN bit must be cleared, and a minimum time $t_{d(PU-ADV)}$, (see the specific device data sheet for actual value) has to be allowed before starting a new conversion. This wait must be implemented in the application software.

Copyright © 2018, Texas Instruments Incorporated

22.2.6.3.2 Enhanced Power-Down Mode

A bit in the ADC operating mode control register, IDLE_PWRDN (ADOPMODECR.4) enables the enhanced power-down mode of the ADC.

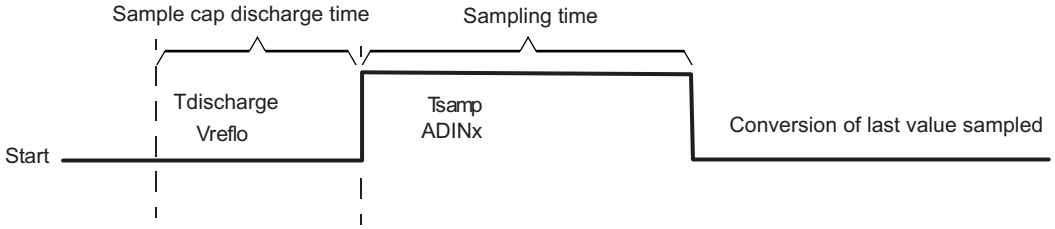
Once this bit is set, the ADC module will power down the ADC core whenever there are no more ongoing or pending ADC conversions. The ADC core will be powered down regardless of the state of the POWERDOWN bit (ADOPMODECR.3).

The ADC module releases the ADC core from power down mode as soon as a new conversion is requested. The ADC logic state machine then has to wait for at least $t_{d(PU-ADV)}$ (see the device data sheet for actual value) before starting a new conversion. The IDLE_PWRDN bit will remain set at all times. The logic state machine can use this bit to determine that it needs to wait for a programmable number of VCLK cycles before it allows the input channel to be sampled. This time is configured by the ADC Power Up Delay Control register (ADPWRUPDLYCTRL).

If IDLE_PWRDN is not set, the ADC module does not wait for any additional delay before sampling the input channel and the application software has to take account of this required delay.

22.2.6.3.3 Managing Clocks to the ADC Module

The clock to the ADC module can be turned off via the appropriate Peripheral Central Resource (PCR) controller PSPWRDNSET register (check the specific device datasheet to identify the register and the bit to be set). If a conversion is ongoing when this bit is set, the ADC module will wait until the current conversion completes before allowing the ADC module clock to be stopped.



22.2.6.4 ADC Sample Capacitor Discharge Mode

This mode allows the charge on the ADC core's internal sampling capacitor to be discharged before starting the sampling phase of the next channel.

The ADC Sample Cap Discharge Mode is enabled by setting the SAMP_DIS_EN bit of the group's ADSAMPDISEN register. A discharge period for the sampling capacitor is added before the sampling period for each channel as shown in Figure 22-17. The duration of this discharge period is configurable via the corresponding group's_SAMP_DIS_CYC field in the ADSAMPDISEN register. The discharge time is specified in terms of number of ADCLK cycles.

During the sample capacitor discharge period, the V_{REFLO} reference voltage is connected to the input voltage terminal of the ADC core. This allows any charge collected on the sampling capacitor from the previous conversion to be discharged to ground. The V_{REFLO} reference voltage is usually connected to ground.

Figure 22-17. Timing for Sample Capacitor Discharge Mode

22.2.7 ADC Results' RAM Special Features

The following section describes some of the special features supported by the ADC module to enhance the results' RAM testability and integrity.

22.2.7.1 ADC Results' RAM Auto-Initialization

The ADC module allows the application to auto-initialize the ADC results' RAM to all zeros. The application must ensure that the ADC module is not in any of the conversion modes before triggering off the auto-initialization process.

The auto-initialization sequence is as follows:

1. Enable the global hardware memory initialization key by programming a value of 1010 to the bits [3-0] of the MINITGCR register of the System module.
2. Set the control bit for the ADC results' RAM in the MSINENA System module register. The bit 8 of the MSINENA register is used to control the initialization of the ADC1 results' RAM, while bit 14 controls the initialization of the ADC2 results' RAM. This starts the initialization process. The BUF_INIT_ACTIVE flag in the ADBNDEND register will get set to reflect that the initialization is ongoing.
3. When the memory initialization is completed, the corresponding status bit in the MINISTAT register will be set. Also, the BUF_INIT_ACTIVE flag will get cleared.

22.2.7.2 ADC Results' RAM Test Mode

In the defined conversion modes of the ADC, the application can only read from the ADC results' RAM. Only the ADC module is allowed to write to the results' RAM. A special test mode is defined to allow the application to also write into the ADC results' RAM - this mode is the ADC Results' RAM Test Mode. Only 32-bit reads and writes are allowed to the ADC results' RAM in this test mode.

NOTE: Contention on access to ADC Results' RAM

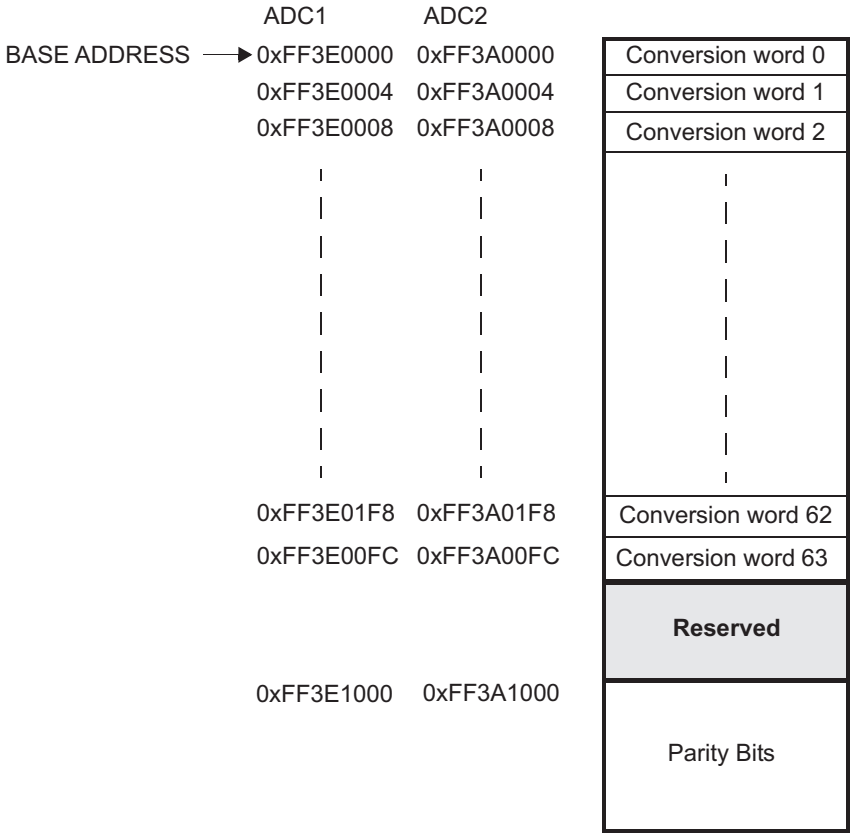
The ADC module cannot handle a contention between the application write to the results' RAM and the ADC writing a conversion result to the results' RAM. The application must ensure that the ADC is not likely to write a new conversion result to the results' RAM when the ADC Results' RAM Test Mode is enabled.

The ADC Results' RAM Test Mode is enabled by setting the RAM_TEST_EN bit in the ADOPMODECR.

22.2.7.3 ADC Results' RAM Parity

The following shows the ADC Results' RAM parity control registers.

Parity checking is implemented using parity on a per-half word basis for the ADC RAM. That is, there is one parity bit for 16 bits of the ADC RAM. The polarity of the ADC RAM parity is controlled by the DEVCR1 register in the system module (address = 0xFFFFFFDC). The parity checking is enabled by the ADPARCR register. After reset, the parity checking is disabled and must be enabled if parity protection is required.



During a read access, the parity is calculated based on the data read from the ADC RAM and compared with the good parity value stored in the parity bits. If any word fails the parity check then the ADC generates an error signal hooked up to the Error Signaling Module (ESM). The ADC RAM address which generated the parity error is captured for host system debugging, and is frozen from being updated until it is read by the application.

Testing the Parity Checking Mechanism:

To test the parity checking mechanism itself, the parity RAM is made writable by the CPU in a special test mode. This is done by a control bit called TEST in the AD PAR CR register. Once this bit is set, the parity bits are mapped to an address starting at an address offset of 4KB from the base address of the ADC RAM. See Figure 22-18. The CPU can now manually insert parity errors. Note that the ADC RAM only supports 32-bit accesses.

22.2.8 ADEVT Pin General Purpose I/O Functionality

The AD1EVT pin for ADC1 and AD2EVT pin for ADC2 can be configured as general-purpose I/O signals. The following sections describe the different ways in which the application can configure the ADxEVT pins.

22.2.8.1 GPIO Functionality

Figure 22-19 illustrates the GPIO functionality of the ADxEVT pin.

Figure 22-19. GPIO Functionality of ADxEVT

Copyright © 2018, Texas Instruments Incorporated

Once the device power-on reset is released, the ADC module controls the state of the ADxEVT pin.

- **Pull control:** The pull control can either be enabled or disabled by default (while system reset is active and after it is released). The actual default state of the pull control is specified in the device datasheet. The application can enable pull control by clearing the PDIS (pull control disable) bit in the ADEVTPDIS register. In this case, if the PSEL (pull select) bit in the ADEVTPSEL register is set, the pin will have a pull-up. If the PSEL bit is cleared, the pin will have a pull-down. If the PDIS bit is set in the control register, there is no pull-up or pull-down on the pin.

NOTE: Pull Behavior when ADxEVT is configured as output

If the ADxEVT pin is configured as output, then the pulls are disabled automatically. If the pin is configured as input, the pulls are enabled or disabled depending on bit PDIS in the pull disable register ADEVTPDIS.

- **Output buffer:** The ADxEVT pin can be driven as an output pin if the ADEVTDIR bit is set in the pin direction control register.
- **Open-Drain Feature:** The open drain output capability is enabled via the ADEVTPDR control register. The ADxEVT pin must be also configured to be an output pin for this mode.
  - The output buffer is enabled if a low signal is being driven on to the pin.
  - The output buffer is disabled if a high signal is being driven on to the pin.

22.2.8.2 Summary

The behavior of the output buffer, and the pull control is summarized in Table 22-5. The input buffer for the ADxEVT pins are enabled once the device power-on reset is released.

Table 22-5. Output Buffer and Pull Control Behavior for ADxEVT as GPIO Pins

System Reset Active?	Pin Direction (DIR) [1][2]	Pull Disable (PDIS) [1] [3]	Pull Select (PSEL) [1] [4]	Pull Control	Output Buffer
Yes	X	X	X	Enabled	Disabled
No	0	0	0	Pull down	Disabled
No	0	0	1	Pull up	Disabled
No	0	1	0	Disabled	Disabled
No	0	1	1	Disabled	Disabled
No	1	X	X	Disabled	Enabled

(1) X = Don't care
(2) DIR = 0 for input, 1 for output
(3) PULDIS = 0 for enabling pull control, 1 for disabling pull control
(4) PULSEL = 0 for pull-down functionality, 1 for pull-up functionality

22.3 ADC Registers

All registers in the ADC module are 32-bit, word-aligned; 8-bit, 16-bit and 32-bit accesses are allowed. The application must ensure that the reserved bits are always written as 0 to ensure software compatibility to future revisions of the module. Table 22-6 shows register address offsets from the base address of the ADC modules. The base address of ADC1 registers is FFF7 C000h and the base address of ADC2 registers is FFF7 C200h.

Table 22-8. ADC Operating Mode Control Register (ADOPMODECR) Field Descriptions

Bit	Field	Value	Description
31	10_12_BIT		This bit controls the resolution of the ADC core. It also affects the size of the conversion results stored in the results' RAM.
			Any operation mode read/write:
		0	The ADC core and digital logic are configured to be in 10-bit resolution. This is the default mode of operation.
		1	The ADC core and digital logic are configured to be in 12-bit resolution.
30-25	Reserved	0	Reads return 0. Writes have no effect.

Copyright © 2018, Texas Instruments Incorporated

Table 22-8. ADC Operating Mode Control Register (ADOPMODECR) Field Descriptions (continued)

Bit	Field	Value	Description
24	COS		This bit affects *emulation operation only*. It defines whether the ADC core clock (ADCLK) is immediately halted when the emulation system enters suspend mode or if it should continue operating normally.
			Note: If COS = 0 when the ADC module enters the emulation mode, then the accuracy of the conversion results can be affected depending on how long the module stays in the emulation mode.
			Any operation mode read/write:
		0	ADC module halts all ongoing conversions immediately after emulation mode is entered.
		1	ADC module continues all ongoing conversions as per the configurations of the three conversion groups.
23-21	Reserved	0	Reads return 0. Writes have no effect.
20-17	CHN_TEST_EN		Enable the input channels' impedance measurement mode.
			This mode is reserved for use by TI.
			Any operation mode read/write:
		Ah	Input impedance measurement mode is disabled.
		5h	Input impedance measurement mode is enabled.
		other values	Input impedance measurement mode is disabled.
16	RAM_TEST_EN		Enable the ADC Results' RAM Test Mode.
			Refer to Section 22.2.7.2 for more details.
			Any operation mode read/write:
		0	ADC RAM Test Mode is disabled. The application cannot write to the ADC RAM by the CPU or the DMA.
		1	ADC RAM Test Mode is enabled. The application can directly write to the ADC RAM by the CPU or the DMA.
15-9	Reserved	0	Reads return 0. Writes have no effect.
8	POWERDOWN		ADC Power Down. This bit powers down only the ADC core; the digital logic in the sequencer stays active. To release the core from power down mode, this bit must be cleared. If a conversion is ongoing, the ADC module will wait until the current conversion is completed before powering down the ADC core.
			Also refer to Section 22.3.68, ADC Power-Up Delay Control Register (ADPWRUPDLYCTRL).
			Any operation mode read/write:
		0	The state of the ADC core is controlled by the IDLE_PWRDN bit, or by a global power down mode entry.
		1	ADC core is in the power-down state.
7-5	Reserved	0	Reads return 0. Writes have no effect.
4	IDLE_PWRDN		ADC Power Down When Idle. When this bit is set, the ADC module will automatically power down the ADC core whenever there are no conversions ongoing or pending. This is the enhanced power down mode.
			Also refer to Section 22.3.68, ADC Power-Up Delay Control Register (ADPWRUPDLYCTRL).
			Any operation mode read/write:
		0	The ADC stays in the normal operating mode even if no conversions are ongoing or pending. The power down state is entered only by configuring the POWER DOWN bit or via a global power down mode entry.
		1	Enhanced power down mode is enabled.
3-1	Reserved	0	Reads return 0. Writes have no effect.
0	ADC_EN		ADC Enable. This bit must be set to allow the ADC module to be configured to perform any conversions.
			Any operation mode read/write:
		0	No ADC conversions can occur. The input channel select registers: ADEVSEL, ADG1SEL, and ADG2SEL are held at their reset values.
		1	ADC conversions can now proceed as configured.

22.3.3 ADC Clock Control Register (ADCLOCKCR)

Figure 22-22 and Table 22-9 describe the ADCLOCKCR register.

Figure 22-22. ADC Clock Control Register (ADCLOCKCR) [offset = 08h]

31	5	4	0
Reserved		PS	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-9. ADC Clock Control Register (ADCLOCKCR) Field Descriptions

Bit	Field	Value	Description
31-5	Reserved	0	Reads return 0. Writes have no effect.
4-0	PS	0-1Fh	ADC Clock Prescaler. These bits define the prescaler value for the ADC core clock (ADCLK). The ADCLK is generated by dividing down the input bus clock (VCLK) to the ADC module. **Note:** The supported range for the ADC clock frequency is specified in the device datasheet. The ADC clock prescaler must be configured to meet this datasheet specification. Any operation mode read/write: $t_{C(ADCLK)} = t_{C(VCLK)} \times (PS[4:0] + 1)$, where $t_{C(ADCLK)}$ is the period of the ADCLK and $t_{C(VCLK)}$ is the period of the VCLK.

22.3.4 ADC Calibration Mode Control Register (ADCALCR)

Figure 22-23 and Table 22-10 describe the ADCALCR register.

Figure 22-23. ADC Calibration Mode Control Register (ADCALCR) [offset = 0Ch]

Reserved		SELF_TEST
R-0		R/W-0

23	17	16
Reserved		CAL_ST
R-0		R/S-0

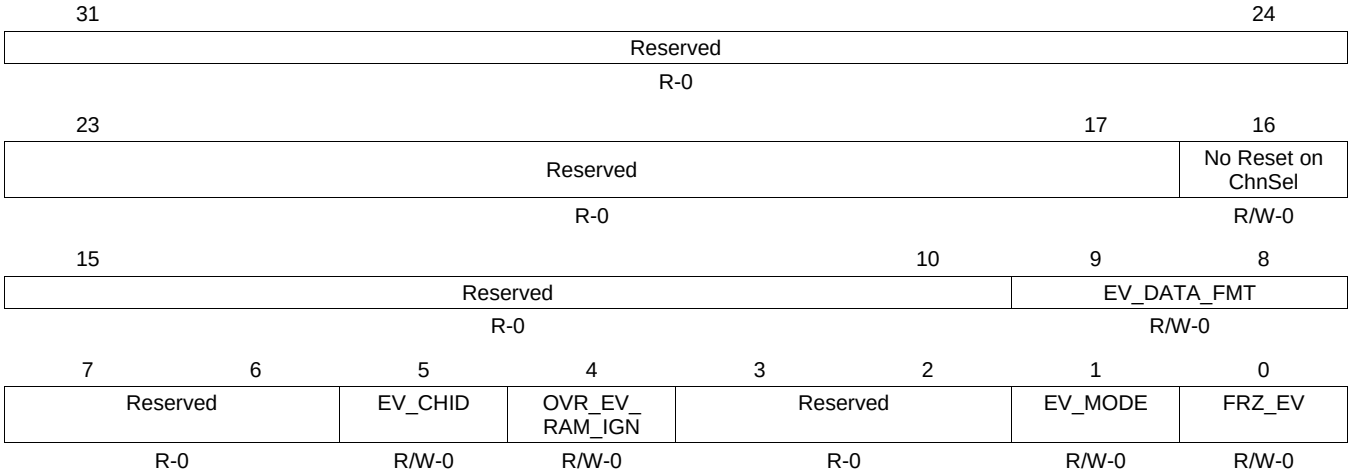
15	10	9	8
Reserved		BRIDGE_EN	HILO
R-0		R/W-0	R/W-0

7	1	0
Reserved		CAL_EN
R-0		R/W-0

LEGEND: R/W = Read/Write; R = Read only; S = Set; -*n* = value after reset

Copyright © 2018, Texas Instruments Incorporated

Table 22-10. ADC Calibration Mode Control Register (ADCALCR) Field Descriptions



Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24	SELF_TEST		ADC Self Test Enable. When this bit is Set, either AD_{REFHI} or AD_{REFLO} is connected through a resistor to the selected input channel. The desired conversion mode is configured in the group mode control registers. For more details on the ADC Self Test Mode, refer to Section 22.2.6.2.
			Any operation mode read/write:
		0	ADC Self Test mode is disabled.
		1	ADC Self Test mode is enabled.
23-17	Reserved	0	Reads return 0. Writes have no effect.
16	CAL_ST		ADC Calibration Conversion Start. Setting the CAL_ST bit while the CAL_EN bit is set starts conversion of the selected reference voltage. The ADC module uses the sample time configured in the Event Group sample time configuration register (ADEVSAMP) for the calibration conversion.
			Any operation mode:
		0	Read: Calibration conversion has completed, or has not yet been started.
			Write: No effect.
		1	Read: Calibration conversion is in progress.
			Write: ADC module starts calibration conversion.
15-10	Reserved	0	Reads return 0. Writes have no effect.
9	BRIDGE_EN		Bridge Enable. When set with the HILO bit, BRIDGE_EN allows a reference voltage to be converted in calibration mode. Table 22-2 defines the four different reference voltages that can be selected.
8	HILO		ADC Self Test mode and Calibration Mode Reference Source Selection.
			In the ADC Self Test mode, this bit defines the test voltage to be combined through a resistor with the selected input pin voltage. Refer to Section 22.2.6.2 for details on the ADC Self Test Mode.
			In the ADC Calibration Mode, this bit defines the reference source polarity. Refer to Section 22.2.6.1 for details on the ADC Calibration Mode.
			In the ADC module's normal operating mode, this bit has no effect.
7-1	Reserved	0	Reads return 0. Writes have no effect.
0	CAL_EN		ADC Calibration Enable. When this bit is set, the input channel multiplexor is disconnected and the calibration reference voltage is connected to the ADC core input. The calibration reference voltage is selected by the combination of the BRIDGE_EN and HILO. The actual conversion of this reference voltage starts when the CAL_ST bit is set. If the CAL_ST bit is already set when the CAL_EN bit is set, then the calibration conversion is immediately started.
			Refer to Section 22.2.6.1 for more details on the ADC calibration mode.
			Any operation mode read/write:
		0	Calibration mode is disabled.
		1	Calibration mode is enabled.

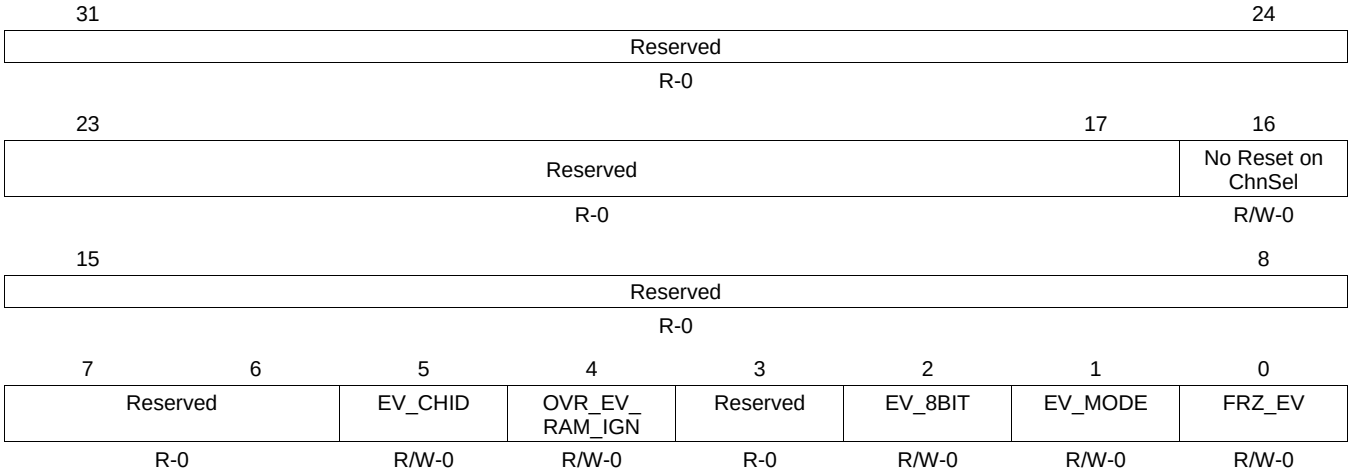
22.3.5 ADC Event Group Operating Mode Control Register (ADEVMODECR)



ADC Event Group Operating Mode Control Register (ADEVMODECR) is shown in Figure 22-24 and Figure 22-25, and described in Table 22-11. As shown, the format of the ADEVMODECR is different based on whether the ADC module is configured to be a 12-bit or a 10-bit ADC module.

Figure 22-24. 12-bit ADC Event Group Operating Mode Control Register (ADEVMODECR) [offset = 10h]

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Figure 22-25. 10-bit ADC Event Group Operating Mode Control Register (ADEVMODECR) [offset = 10h]

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Copyright © 2018, Texas Instruments Incorporated

Table 22-11. ADC Event Group Operating Mode Control Register (ADEVMODECR) Field Descriptions

Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
No Reset on ChnSel		No Event Group Results Memory Reset on New Channel Select. This bit determines whether the event group results' RAM is reset whenever a non-zero value is written to the event group channel select register. Any operation mode read/write:
	0	Event group results RAM is reset when a non-zero value is written to event group channel select register, even if event group conversions are completed.
	1	Event group results RAM is not reset when a non-zero value is written to event group channel select register, and event group conversions are completed. If the event group conversions are ongoing (active or frozen), then writing a non-zero value to the event group channel select register will always reset the event group results RAM.
EV_DATA_FMT		Event Group Read Data Format. This field is only applicable when the ADC module is configured to be in the 12-bit ADC module. This field is reserved when the module is configured as a 10-bit ADC module. This field determines the format in which the conversion results are read out of the Event group results RAM when using the FIFO interface, that is, when reading from the ADEVBUFFER or ADEVEMUBUFFER locations. Any operation mode read/write:
	0	Conversion results are read out in full 12-bit format. This is the default mode.
	1h	Conversion results are read out in 10-bit format. Bits 11-2 of the 12-bit conversion result are returned as the 10-bit conversion result.
	2h	Conversion results are read out in 8-bit format. Bits 11-4 of the 12-bit conversion result are returned as the 8-bit conversion result.
	3h	Reserved. The full 12-bit conversion result is returned if programmed.
EV_CHID		Enable Channel Id for the Event Group conversion results to be read. This bit only affects the "read from FIFO" mode. The ADC always stores the channel id in the results RAM. Any 16-bit read performed in the "read from RAM" mode will return the 5-bit channel id along with the 10-bit conversion result. Any operation mode read/write:
	0	Bits 14-10, the channel id field, of the data read from the Event Group results' FIFO is read as 00000b.
	1	Bits 14-10, the channel id field, of the data read from the Event Group results' FIFO contains the number of the ADC analog input to which the conversion result belongs.
OVR_EV_RAM_IGN		This bit allows the ADC module to overwrite the contents of the Event Group results memory under an overrun condition. Any operation mode read/write:
	0	The ADC cannot overwrite the contents of the Event Group results memory. When an overrun of this memory occurs, the software needs to read out all the contents of this memory before the ADC is able to write a new conversion result for the Event Group.
	1	When an overrun of the Event Group results memory occurs, the ADC proceeds to overwrite the contents with any new conversion results for the Event Group, starting with the first location in this memory.
EV_8BIT		Event Group 8-bit result mode. This bit is only applicable when the ADC module is configured to be a 10-bit ADC module. This field is reserved when the module is configured as a 12-bit ADC module. This bit allows the Event Group conversion results to be read out in an 8-bit format. This bit only applies to the "read from FIFO" mode. The lower 2 bits of the 10-bit conversion result are discarded and the upper 8 bits are shifted right two places to form the 8-bit conversion result. Any operation mode read/write:
	0	The Event Group conversion result is read out as a 10-bit value in the "read from Event Group FIFO" mode.
	1	The Event Group conversion result is read out as an 8-bit value in the "read from Event Group FIFO" mode.

Copyright © 2018, Texas Instruments Incorporated

Table 22-11. ADC Event Group Operating Mode Control Register (ADEVMODECR) Field Descriptions (continued)

Field	Value	Description
EV_MODE		Event Group Conversion Mode. This bit defines whether the input channels selected for conversion in the Event Group are converted only once per trigger, or are continuously converted. Any operation mode read/write:
	0	The channels selected for conversion in the Event Group are converted only once when the selected event trigger condition occurs.
	1	The channels selected for conversion in the Event Group are converted continuously when the selected event trigger condition occurs.
FRZ_EV		Event Group Freeze Enable. This bit allows an Event Group conversion sequence to be frozen if a Group1 or a Group2 conversion is requested. The Event Group conversion is kept frozen while the Group1 or Group2 conversion is active, and continues from where it was frozen once the Group1 or Group2 conversions are completed. While the Event Group conversion is frozen, the EV_STOP status flag in the ADEVSR register indicates that the Event Group conversions have stopped. This bit gets cleared when the Event Group conversions resume. Any operation mode read/write:
	0	Event Group conversions cannot be frozen. All the channels selected for conversion in the Event Group are converted before the ADC can switch over to servicing any other conversion group.
	1	Event Group conversions are frozen whenever there is a request for conversion from Group1 or Group2.

22.3.6 ADC Group1 Operating Mode Control Register (ADG1MODECR)

ADC Group1 Operating Mode Control Register (ADG1MODECR) is shown in Figure 22-26 and Figure 22-27, and described in Table 22-12. As shown, the format of the ADG1MODECR is different based on whether the ADC module is configured to be a 12-bit or a 10-bit ADC module.

Table 22-12. ADC Group1 Operating Mode Control Register (ADG1MODECR) Field Descriptions

Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
No Reset on ChnSel		No Group1 Results Memory Reset on New Channel Select. This bit determines whether the group1 results' RAM is reset whenever a non-zero value is written to the group1 channel select register. Any operation mode read/write:
	0	Group1 results RAM is reset when a non-zero value is written to group1 channel select register, even if group1 conversions are completed.
	1	Group1 results RAM is not reset when a non-zero value is written to group1 channel select register, and group1 conversions are completed. If the group1 conversions are ongoing (active or frozen), then writing a non-zero value to the group1 channel select register will always reset the group1 results RAM.
G1_DATA_FMT		Group1 Read Data Format. This field is only applicable when the ADC module is configured to be in the 12-bit ADC module. This field is reserved when the module is configured as a 10-bit ADC module. This field determines the format in which the conversion results are read out of the group1 results RAM when using the FIFO interface, that is, when reading from the ADG1BUFFER or ADG1EMUBUFFER locations. Any operation mode read/write:
	0	Conversion results are read out in full 12-bit format. This is the default mode.
	1h	Conversion results are read out in 10-bit format. Bits 11-2 of the 12-bit conversion result are returned as the 10-bit conversion result.
	2h	Conversion results are read out in 8-bit format. Bits 11-4 of the 12-bit conversion result are returned as the 8-bit conversion result.
	3h	Reserved. The full 12-bit conversion result is returned if programmed.
G1_CHID		Enable Channel Id for the Group1 conversion results to be read. This bit only affects the "read from FIFO" mode. The ADC always stores the channel id in the results RAM. Any 16-bit read performed in the "read from RAM" mode will return the 5-bit channel id along with the 10-bit conversion result. Any operation mode read/write:
	0	Bits 14-10, the channel id field, of the data read from the Group1 results' FIFO is read as 00000b.
	1	Bits 14-10, the channel id field, of the data read from the Group1 results' FIFO contains the number of the ADC analog input to which the conversion result belongs.
OVR_G1_RAM_IGN		This bit allows the ADC module to overwrite the contents of the Group1 results memory under an overrun condition. Any operation mode read/write:
	0	The ADC cannot overwrite the contents of the Group1 results memory. When an overrun of this memory occurs, the software needs to read out all the contents of this memory before the ADC is able to write a new conversion result for the Group1.
	1	When an overrun of the Group1 results memory occurs, the ADC proceeds to overwrite the contents with any new conversion results for the Group1, starting with the first location in this memory.
G1_HW_TRIG		Group1 Hardware Triggered. This bit allows the Group1 to be hardware triggered. The Group1 is software triggered by default. For more details on how to trigger a conversion group, refer to Section 22.2.1.6. Any operation mode read/write:
	0	The Group1 is software-triggered. A Group1 conversion starts whenever the Group1 channel select register (ADG1SEL) is written with a non-zero value.
	1	The Group1 is hardware-triggered. A Group1 conversion starts whenever the Group1 channel select register has a non-zero value, and the specified hardware trigger occurs. The hardware trigger for the Group1 is specified in the Group1 Trigger Source register (ADG1SRC).

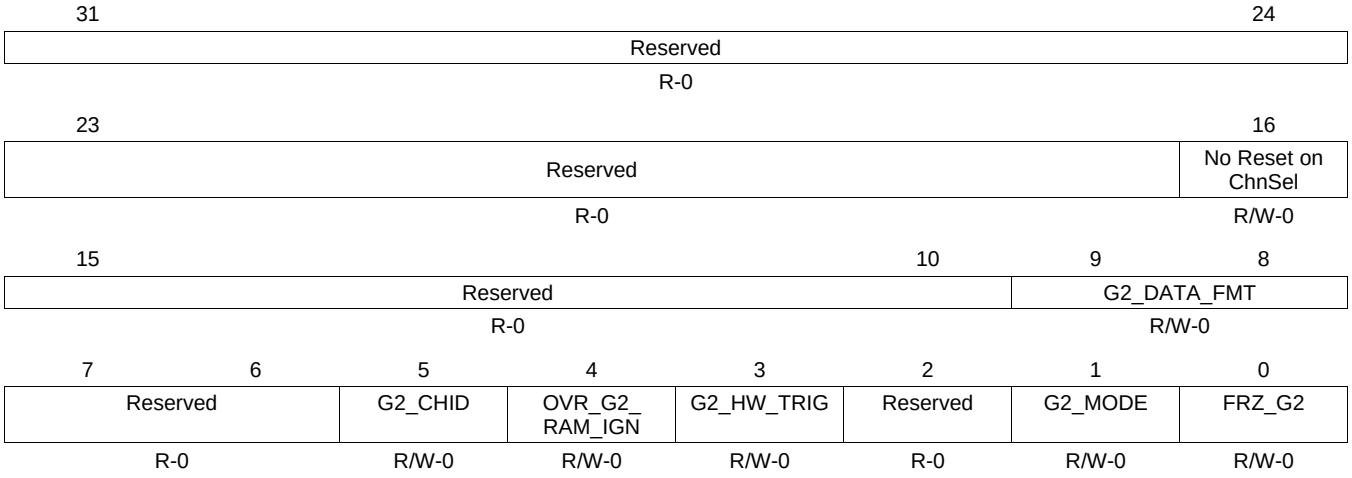
Table 22-12. ADC Group1 Operating Mode Control Register (ADG1MODECR) Field Descriptions (continued)



Field	Value	Description
G1_8BIT		Group1 8-bit result mode. This field is only applicable when the ADC module is configured to be in the 10-bit ADC module. This field is reserved when the module is configured as a 12-bit ADC module. This bit allows the Group1 conversion results to be read out in an 8-bit format. This bit only applies to the “read from FIFO” mode. The lower 2 bits of the 10-bit conversion result are discarded and the upper 8 bits are shifted right two places to form the 8-bit conversion result. Any operation mode read/write:
	0	The Group1 conversion result is read out as a 10-bit value in the “read from Group1 FIFO” mode.
	1	The Group1 conversion result is read out as an 8-bit value in the “read from Group1 FIFO” mode.
G1_MODE		Group1 Conversion Mode. This bit defines whether the input channels selected for conversion in the Group1 are converted only once, or are continuously converted. Any operation mode read/write:
	0	The channels selected for conversion in the Group1 are converted only once.
	1	The channels selected for conversion in the Group1 are converted continuously.
FRZ_G1		Group1 Freeze Enable. This bit allows a Group1 conversion sequence to be frozen if an Event Group or a Group2 conversion is requested. The Group1 conversion is kept frozen while the Event Group or Group2 conversion is active, and continues from where it was frozen once the Event Group or Group2 conversions are completed. While the Group1 conversion is frozen, the G1_STOP status flag in the ADG1SR register indicates that the Group1 conversions have stopped. This bit gets cleared when the Group1 conversions resume. Any operation mode read/write:
	0	Group1 conversions cannot be frozen. All the channels selected for conversion in the Group1 are converted before the ADC can switch over to servicing any other conversion group.
	1	Group1 conversions are frozen whenever there is a request for conversion from Event Group or Group2.

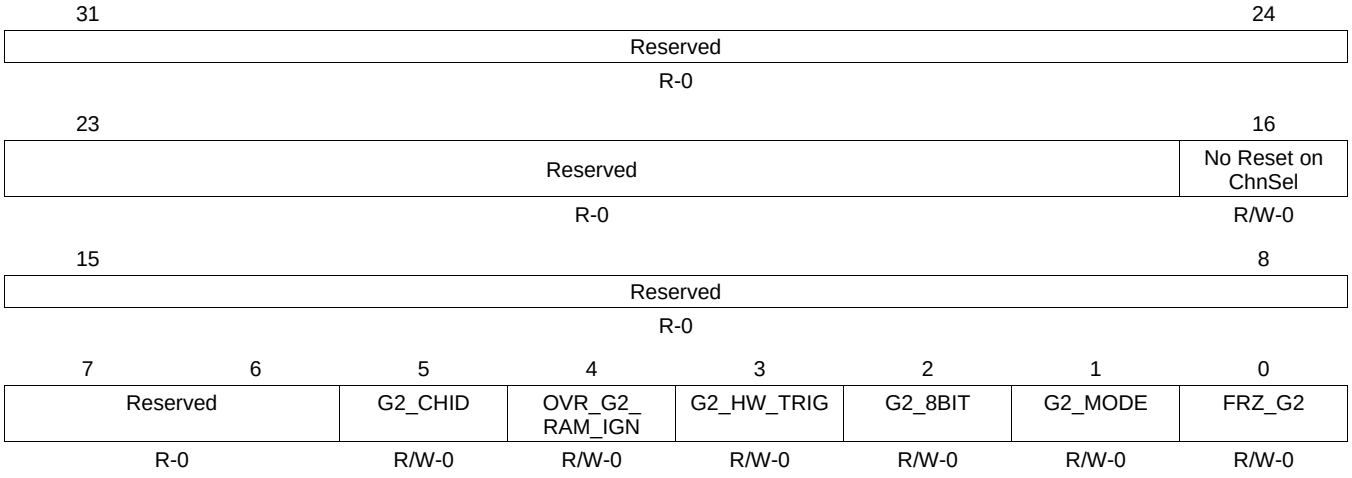
22.3.7 ADC Group2 Operating Mode Control Register (ADG2MODECR)



ADC Group2 Operating Mode Control Register (ADG2MODECR) is shown in Figure 22-28 and Figure 22-29, described in Table 22-13. As shown, the format of the ADG2MODECR is different based on whether the ADC module is configured to be a 12-bit or a 10-bit ADC module.

Figure 22-28. 12-bit ADC Group2 Operating Mode Control Register (ADG2MODECR) [offset = 18h]

Table 22-13. ADC Group 2 Operating Mode Control Register (ADG2MODECR) Field Descriptions

Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
No Reset on ChnSel		No Group2 Results Memory Reset on New Channel Select. This bit determines whether the group2 results' RAM is reset whenever a non-zero value is written to the group2 channel select register. Any operation mode read/write:
	0	Group2 results RAM is reset when a non-zero value is written to group2 channel select register, even if group2 conversions are completed.
	1	Group2 results RAM is not reset when a non-zero value is written to group2 channel select register, and group2 conversions are completed. If the group2 conversions are ongoing (active or frozen), then writing a non-zero value to the group2 channel select register will always reset the group2 results RAM.
G2_DATA_FMT		Group2 Read Data Format. This field is only applicable when the ADC module is configured to be in the 12-bit ADC module. This field is reserved when the module is configured as a 10-bit ADC module. This field determines the format in which the conversion results are read out of the group1 results RAM when using the FIFO interface, that is, when reading from the ADG2BUFFER or ADG2EMUBUFFER locations. Any operation mode read/write:
	0	Conversion results are read out in full 12-bit format. This is the default mode.
	1h	Conversion results are read out in 10-bit format. Bits 11-2 of the 12-bit conversion result are returned as the 10-bit conversion result.
	2h	Conversion results are read out in 8-bit format. Bits 11-4 of the 12-bit conversion result are returned as the 8-bit conversion result.
	3h	Reserved. The full 12-bit conversion result is returned if programmed.
G2_CHID		Enable Channel Id for the Group2 conversion results to be read. This bit only affects the "read from FIFO" mode. The ADC always stores the channel id in the results RAM. Any 16-bit read performed in the "read from RAM" mode will return the 5-bit channel id along with the 10-bit conversion result. Any operation mode read/write:
	0	Bits 14-10, the channel id field, of the data read from the Group2 results' FIFO is read as 00000b.
	1	Bits 14-10, the channel id field, of the data read from the Group2 results' FIFO contains the number of the ADC analog input to which the conversion result belongs.
OVR_G2_RAM_IGN		This bit allows the ADC module to overwrite the contents of the Group2 results memory under an overrun condition. Any operation mode read/write:
	0	The ADC cannot overwrite the contents of the Group2 results memory. When an overrun of this memory occurs, the software needs to read out all the contents of this memory before the ADC is able to write a new conversion result for the Group2.
	1	When an overrun of the Group2 results memory occurs, the ADC proceeds to overwrite the contents with any new conversion results for the Group2, starting with the first location in this memory.
G2_HW_TRIG		Group2 Hardware Triggered. This bit allows the Group2 to be hardware triggered. The Group2 is software triggered by default. For more details on how to trigger a conversion group, refer to Section 22.2.1.6. Any operation mode read/write:
	0	The Group2 is software-triggered. A Group2 conversion starts whenever the Group2 channel select register (ADG2SEL) is written with a non-zero value.
	1	The Group2 is hardware-triggered. A Group2 conversion starts whenever the Group2 channel select register has a non-zero value, and the specified hardware trigger occurs. The hardware trigger for the Group2 is specified in the Group2 Trigger Source register (ADG2SRC).

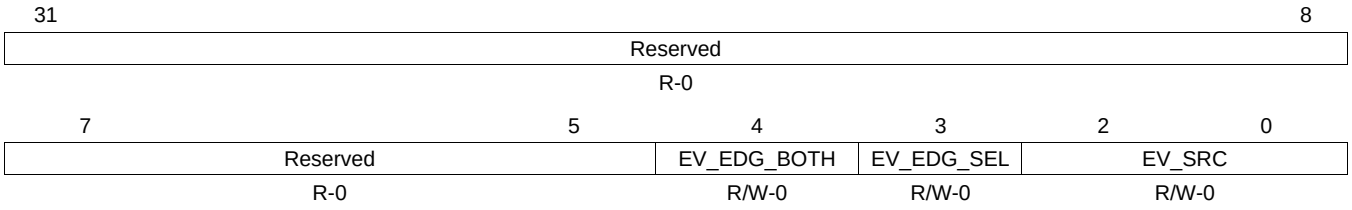
Table 22-13. ADC Group 2 Operating Mode Control Register (ADG2MODECR) Field Descriptions (continued)



Field	Value	Description
G2_8BIT		Group2 8-bit result mode. This field is only applicable when the ADC module is configured to be in the 10-bit ADC module. This field is reserved when the module is configured as a 12-bit ADC module. This bit allows the Group2 conversion results to be read out in an 8-bit format. This bit only applies to the “read from FIFO” mode. The lower 2 bits of the 10-bit conversion result are discarded and the upper 8 bits are shifted right two places to form the 8-bit conversion result. Any operation mode read/write:
	0	The Group2 conversion result is read out as a 10-bit value in the “read from Group2 FIFO” mode.
	1	The Group2 conversion result is read out as an 8-bit value in the “read from Group2 FIFO” mode.
G2_MODE		Group2 Conversion Mode. This bit defines whether the input channels selected for conversion in the Group2 are converted only once, or are continuously converted. Any operation mode read/write:
	0	The channels selected for conversion in the Group2 are converted only once.
	1	The channels selected for conversion in the Group2 are converted continuously.
FRZ_G2		Group2 Freeze Enable. This bit allows a Group2 conversion sequence to be frozen if an Event Group or a Group1 conversion is requested. The Group2 conversion is kept frozen while the Event Group or Group1 conversion is active, and continues from where it was frozen once the Event Group or Group1 conversions are completed. While the Group2 conversion is frozen, the G2_STOP status flag in the ADG2SR register indicates that the Group2 conversions have stopped. This bit gets cleared when the Group2 conversions resume. Any operation mode read/write:
	0	Group2 conversions cannot be frozen. All the channels selected for conversion in the Group2 are converted before the ADC can switch over to servicing any other conversion group.
	1	Group2 conversions are frozen whenever there is a request for conversion from Event Group or Group1.

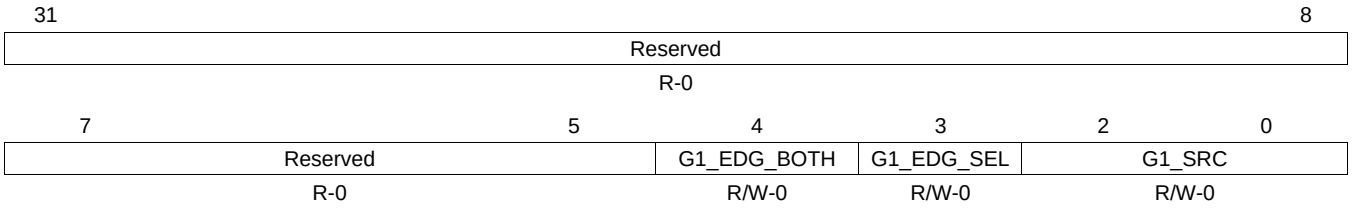
22.3.8 ADC Event Group Trigger Source Select Register (ADEVSRC)

ADC Event Group Trigger Source Select Register (ADEVSRC) is shown in Figure 22-30 and described in Table 22-14.

Figure 22-30. ADC Event Group Trigger Source Select Register (ADEVSRC) [offset = 1Ch]

LEGEND: R/W = Read/Write; R = Read only; *-n* = value after reset

Table 22-14. ADC Event Group Trigger Source Select Register (ADEVSRC) Field Descriptions



Bit	Field	Value	Description
31-5	Reserved	0	Reads return 0. Writes have no effect.
4	EV_EDG_BOTH		EV Group Trigger Edge Polarity Select. This bit configures the event group to be triggered on both rising and falling edge detected on the selected trigger source.
			Any operation mode read/write:
		0	The conversion is triggered only upon detecting an edge defined by the EV_EDG_SEL bit.
		1	The conversion is triggered upon detecting either a rising or falling edge.
3	EV_EDG_SEL		Event Group Trigger Edge Polarity Select. This bit determines the polarity of the transition on the selected source that triggers the Event Group conversion.
			Any operation mode read/write:
		0	A high-to-low transition on the selected source will trigger the Event Group conversion.
		1	A low-to-high transition on the selected source will trigger the Event Group conversion.
2-0	EV_SRC		Event Group Trigger Source.
			Any operation mode read/write:
		0-7h	The ADC module allows a trigger source to be selected for the Event Group from up to eight options. These options are device-specific and the device specification must be referred to identify the actual trigger sources.

Copyright © 2018, Texas Instruments Incorporated

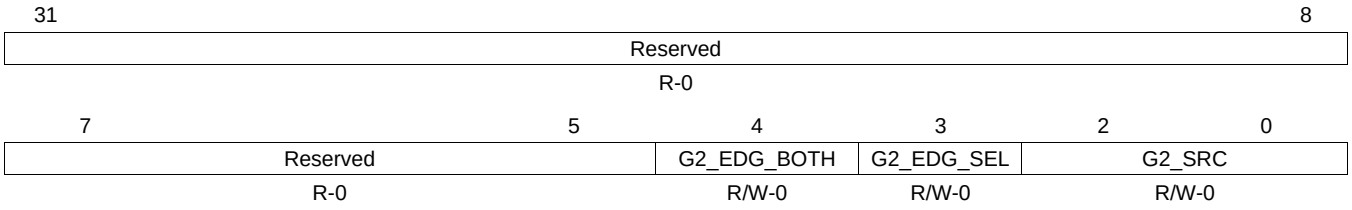
22.3.9 ADC Group1 Trigger Source Select Register (ADG1SRC)

ADC Group1 Trigger Source Select Register (ADG1SRC) is shown in Figure 22-31 and described in Table 22-15.

Figure 22-31. ADC Group1 Trigger Source Select Register (ADG1SRC) [offset = 20h]

LEGEND: R/W = Read/Write; R = Read only; *-n* = value after reset

Table 22-15. ADC Group1 Trigger Source Select Register (ADG1SRC) Field Descriptions



Bit	Field	Value	Description
31-5	Reserved	0	Reads return 0. Writes have no effect.
4	GI_EDG_BOTH		Group1 Trigger Edge Polarity Select. This bit configures the group1 to be triggered on both rising and falling edge detected on the selected trigger source.
			Any operation mode read/write:
		0	The conversion is triggered only upon detecting an edge defined by the G1_EDG_SEL bit.
		1	The conversion is triggered upon detecting either a rising or falling edge.
3	G1_EDG_SEL		Group1 Trigger Edge Polarity Select. This bit determines the polarity of the transition on the selected source that triggers the Group1 conversion.
			Any operation mode read/write:
		0	A high-to-low transition on the selected source will trigger the Group1 conversion.
		1	A low-to-high transition on the selected source will trigger the Group1 conversion.
2-0	G1_SRC		Group1 Trigger Source.
			Any operation mode read/write:
		0-7h	The ADC module allows a trigger source to be selected for the Group1 from up to eight options. These options are device-specific and the device specification must be referred to identify the actual trigger sources.

Copyright © 2018, Texas Instruments Incorporated

22.3.10 ADC Group2 Trigger Source Select Register (ADG2SRC)

ADC Group2 Trigger Source Select Register (ADG2SRC) is shown in Figure 22-32 and described in Table 22-16.

Figure 22-32. ADC Group2 Trigger Source Select Register (ADG2SRC) [offset = 24h]

LEGEND: R/W = Read/Write; R = Read only; *-n* = value after reset

Table 22-16. ADC Group2 Trigger Source Select Register (ADG2SRC) Field Descriptions

Bit	Field	Value	Description
31-5	Reserved	0	Reads return 0. Writes have no effect.
4	G2_EDG_BOTH		Group2 Trigger Edge Polarity Select. This bit configures the group2 to be triggered on both rising and falling edge detected on the selected trigger source.
			Any operation mode read/write:
		0	The conversion is triggered only upon detecting an edge defined by the G2_EDG_SEL bit.
		1	The conversion is triggered upon detecting either a rising or falling edge.
3	G2_EDG_SEL		Group2 Trigger Edge Polarity Select. This bit determines the polarity of the transition on the selected source that triggers the Group2 conversion.
			Any operation mode read/write:
		0	A high-to-low transition on the selected source will trigger the Group2 conversion.
		1	A low-to-high transition on the selected source will trigger the Group2 conversion.
2-0	G2_SRC		Group2 Trigger Source.
			Any operation mode read/write:
		0-7h	The ADC module allows a trigger source to be selected for the Group2 from up to eight options. These options are device-specific and the device specification must be referred to identify the actual trigger sources.

Table 22-20. ADC Event Group Interrupt Flag Register (ADEVINTFLG) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reads return 0. Writes have no effect.
3	EV_END		Event Group Conversion End. This bit will be set only if the Event Group conversions are configured to be in the single-conversion mode. Any operation mode read: 0 All the channels selected for conversion in the Event Group have not yet been converted. 1 All the channels selected for conversion in the Event Group have been converted. An Event Group conversion end interrupt is generated, if enabled, when this bit gets set. This bit can be cleared by any one of the following ways: • By writing a 1 to this bit • By writing a 1 to the Event Group status register (ADEVSR) bit 0 (EV_END) • By reading one conversion result from the Event Group results' memory in the "read from FIFO" mode • By writing a new set of channels to the Event Group channel select register
2	EV_MEM_EMPTY		Event Group Results Memory Empty. This is a read-only bit; writes have no effect. It is not a source of an interrupt from the ADC module. Any operation mode read: 0 The Event Group results memory is not empty. 1 The Event Group results memory is empty.
1	EV_MEM_OVERRUN		Event Group Memory Overrun. This is a read-only bit; writes have no effect. Any operation mode read: 0 Event Group results memory has not overrun. 1 Event Group results memory has overrun.
0	EV_THR_INT_FLG		Event Group Threshold Interrupt Flag. Any operation mode read: 0 The number of conversions completed for the Event Group is smaller than the threshold programmed in the Event Group interrupt threshold register. 1 The number of conversions completed for the Event Group is equal to or greater than the threshold programmed in the Event Group interrupt threshold register. This bit can be cleared by writing a 1; writing a 0 has no effect.

22.3.17 ADC Event Group Threshold Interrupt Control Register (ADEVTHRINTCR)

ADC Event Group Threshold Interrupt Control Register (ADEVTHRINTCR) is shown in Figure 22-39 and described in Table 22-23.

Figure 22-39. ADC Event Group Threshold Interrupt Control Register (ADEVTHRINTCR) [offset = 40h]

31 16	15 9	8 0
Reserved	Sign Extension	EV_THR
R-0	R-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-23. ADC Event Group Threshold Interrupt Control Register (ADEVTHRINTCR) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reads return 0. Writes have no effect.
15-9	Sign Extension		These bits always read the same as EV_THR bit 8 of this register.
8-0	EV_THR		Event Group Threshold Counter. Before ADC conversions begin on the Event Group, this field is initialized to the number of conversion results that the Event Group memory should contain before interrupting the CPU. This counter decrements when the ADC module writes a new conversion result to the Event Group results' memory. The counter increments for each read of a conversion result from the Event Group results' memory in the "read from FIFO" mode. The threshold counter is not affected for a direct read from the Event Group results' memory. Also, a simultaneous ADC write and a CPU/DMA read from the Event Group FIFO will leave the threshold counter unchanged. In case of an Event Group Results' memory overrun condition, if new conversion results are not allowed to overwrite the existing memory contents, then the Event Group threshold counter is not decremented. Refer to Section 22.2.3.2 for more details on the threshold interrupts.

22.3.18 ADC Group1 Threshold Interrupt Control Register (ADG1THRINTCR)

ADC Group1 Threshold Interrupt Control Register (ADG1THRINTCR) is shown in Figure 22-40 and described in Table 22-24.

R-0		R/W-0	R/W-0	R-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; *-n* = value after reset

Table 22-26. ADC Event Group DMA Control Register (ADEVDMACR) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24-16	EV_BLOCKS		Number of Event Group Result buffers to be transferred using DMA if the ADC module is configured to generate a DMA request. If the Event Group is configured to use the block transfer mode of the DMA module, then the ADC module generates a DMA request after the Event Group results' memory accumulates EV_BLOCKS number of conversion results. This feature is designed to be used in place of the threshold interrupt for the Event Group. As a result, the EV_THR field of the Event Group Interrupt Threshold Control Register and the EV_BLOCKS field of the Event Group DMA Control Register are the same. Any operation mode read/write: 0 No DMA transfer occurs even if EV_BLK_XFER is set to 1. 1h-1FFh One DMA request is generated if the EV_BLK_XFER is set to 1 and the specified number of Event Group conversion results have been accumulated.
15-4	Reserved	0	Reads return 0. Writes have no effect.
3	DMA_EV_END		Event Group Conversion End DMA Transfer Enable. Any operation mode read: 0 ADC module generates a DMA request for each write to the Event group results RAM if EV_DMA_EN is set. 1 ADC module generates a DMA request when the ADC has completed the conversions for all channels selected for conversion in the event group. If DMA_EV_END bit is set to 1, EV_DMA_EN bit is ignored and DMA requests will be generated every time the DMA_EV_END flag in the event group status register is set. The DMA_EV_END bit must be set before enabling conversions for the event group.
2	EV_BLK_XFER		Event Group Block DMA Transfer Enable. Any operation mode read: 0 ADC module generates a DMA request for each write to the Event Group memory if EV_DMA_EN is set. 1 ADC module generates a DMA request when the ADC has written EV_BLOCKS number of buffers into the Event Group memory. If EV_BLK_XFER bit is set to 1, EV_DMA_EN bit is ignored and DMA requests will be generated every time the Threshold Counter reaches 0 from a count value of 1.
1	Reserved	0	Reads return 0. Writes have no effect.

Copyright © 2018, Texas Instruments Incorporated

Table 22-26. ADC Event Group DMA Control Register (ADEVDMACR) Field Descriptions (continued)

Bit	Field	Value	Description
0	EV_DMA_EN		Event Group DMA Transfer Enable. Any operation mode read:
		0	ADC module does not generate a DMA request when it writes the conversion result to the Event Group memory.
		1	ADC module generates a DMA transfer when the ADC has written to the Event Group memory. The EV_BLK_XFER bit must be cleared to 0 for this DMA request to be generated.

Table 22-27. ADC Group1 DMA Control Register (ADG1DMACR) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24-16	G1_BLOCKS		Number of Group1 Result buffers to be transferred using DMA if the ADC module is configured to generate a DMA request. If the Group1 is configured to use the block transfer mode of the DMA module, then the ADC module generates a DMA request after the Group1 results' memory accumulates G1_BLOCKS number of conversion results. This feature is designed to be used in place of the threshold interrupt for the Group1. As a result, the G1_THR field of the Group1 Interrupt Threshold Control Register and the G1_BLOCKS field of the Group1 DMA Control Register are the same. Any operation mode read/write:
		0	No DMA transfer occurs even if G1_BLK_XFER is set to 1.
		1h-1FFh	One DMA request is generated if the G1_BLK_XFER is set to 1 and the specified number of Group1 conversion results have been accumulated.
15-4	Reserved	0	Reads return 0. Writes have no effect.
3	DMA_G1_END		Group1 Conversion End DMA Transfer Enable. Any operation mode read:
		0	ADC module generates a DMA request for each write to the group1 results RAM if G1_DMA_EN is set.
		1	ADC module generates a DMA request when the ADC has completed the conversions for all channels selected for conversion in the group1. If DMA_G1_END bit is set to 1, G1_DMA_EN bit is ignored and DMA requests will be generated every time the DMA_G1_END flag in the group 1 status register is set. The DMA_G1_END bit must be set before enabling conversions for the group 1.
2	G1_BLK_XFER		Group1 Block DMA Transfer Enable. Any operation mode read:
		0	ADC module generates a DMA request for each write to the Group1 memory if G1_DMA_EN is set.
		1	ADC module generates a DMA request when the ADC has written G1_BLOCKS number of buffers into the Group1 memory. If G1_BLK_XFER bit is set to 1, G1_DMA_EN bit is ignored and DMA requests will be generated every time the Threshold Counter reaches 0 from a count value of 1.
1	Reserved	0	Reads return 0. Writes have no effect.

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24-16	G2_BLOCKS		Number of Group2 Result buffers to be transferred using DMA if the ADC module is configured to generate a DMA request. If the Group2 is configured to use the block transfer mode of the DMA module, then the ADC module generates a DMA request after the Group2 results' memory accumulates G2_BLOCKS number of conversion results. This feature is designed to be used in place of the threshold interrupt for the Group2. As a result, the G2_THR field of the Group2 Interrupt Threshold Control Register and the G2 BLOCKS field of the Group2 DMA Control Register are the same. Any operation mode read/write: 0 No DMA transfer occurs even if G2_BLK_XFER is set to 1. 1h-1FFh One DMA request is generated if the G2_BLK_XFER is set to 1 and the specified number of Group2 conversion results have been accumulated.
15-4	Reserved	0	Reads return 0. Writes have no effect.
3	DMA_G2_END		Group2 Conversion End DMA Transfer Enable. Any operation mode read: 0 ADC module generates a DMA request for each write to the group2 results RAM if G2_DMA_EN is set. 1 ADC module generates a DMA request when the ADC has completed the conversions for all channels selected for conversion in the group2. If DMA_G2_END bit is set to 1, G2_DMA_EN bit is ignored and DMA requests will be generated every time the DMA_G2_END flag in the group 2 status register is set. The DMA_G2_END bit must be set before enabling conversions for the group 2.
2	G2_BLK_XFER		Group2 Block DMA Transfer Enable. Any operation mode read: 0 ADC module generates a DMA request for each write to the Group2 memory if G2_DMA_EN is set. 1 ADC module generates a DMA request when the ADC has written G2_BLOCKS number of buffers into the Group2 memory. If G2_BLK_XFER bit is set to 1, G2_DMA_EN bit is ignored and DMA requests will be generated every time the Threshold Counter reaches 0 from a count value of 1.
1	Reserved	0	Reads return 0. Writes have no effect.

Copyright © 2018, Texas Instruments Incorporated

Table 22-28. ADC Group2 DMA Control Register (ADG2DMACR) Field Descriptions (continued)

Bit	Field	Value	Description
0	G2_DMA_EN		Group2 DMA Transfer Enable.
			Any operation mode read:
		0	ADC module does not generate a DMA request when it writes the conversion result to the Group2 memory.
		1	ADC module generates a DMA transfer when the ADC has written to the Group2 memory. The G2_BLK_XFER bit must be cleared to 0 for this DMA request to be generated.

22.3.23 ADC Results Memory Configuration Register (ADBNDCR)

ADC Results Memory Configuration Register (ADBNDCR) [offset = 0x58] is shown in Figure 22-45 and described in Table 22-29.

Refer to Section 22.2.7 for further details on how the conversion results are stored in the ADC results' RAM.

Figure 22-45. ADC Results Memory Configuration Register (ADBNDCR) [offset = 58h]

31	25	24	16
Reserved		BNDA	
R-0		R/W-0	

15	9	8	0
Reserved		BNDB	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-29. ADC Results Memory Configuration Register (ADBNDCR) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reads return 0. Writes have no effect.
24-16	BNDA		Buffer Boundary A. These bits determine the memory available for the Event Group conversion results. The memory available is specified in terms of pairs of result buffers.
			Any operation mode read/write:
		0	Event Group conversions are not required. If Event Group conversions are performed with the BNDA value of 0, then the Event Group memory size will default to 1024 words. For proper usage of the ADC results memory, configure the BNDA value to be non-zero and lower than the BNDB value.
		0-1FFh	A total of (2 × BNDA) buffers are available in the ADC results memory for storing Event Group conversion results.
15-9	Reserved	0	Reads return 0. Writes have no effect.
8-0	BNDB		Buffer Boundary B. These bits specify the number of buffers allocated for the Event Group plus the number of buffers allocated for the Group1. The number of buffer pairs allocated for storing Group1 conversion results can be determined by subtracting BNDA from BNDB. As a result, BNDB must always be specified as greater than or equal to BNDA.
			Any operation mode read/write:
		0	Event Group as well as Group1 conversions are not required.
		0-1FFh	A total of 2 × (BNDB - BNDA) buffers are available in the ADC results memory for storing Group1 conversion results.

Copyright © 2018, Texas Instruments Incorporated

22.3.24 ADC Results Memory Size Configuration Register (ADBNDEND)

ADC Results Memory Size Configuration Register (ADBNDEND) is shown in Figure 22-46 and described in Table 22-30.

Figure 22-46. ADC Results Memory Size Configuration Register (ADBNDEND) [offset = 5Ch]

31	17	16
Reserved		BUF_INIT_ACTIVE
R-0		R-0

15	3	2	0
Reserved		BNDEND	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; *-n* = value after reset

Table 22-30. ADC Results Memory Size Configuration Register (ADBNDEND) Field Descriptions

Bit	Field	Value	Description
31-17	Reserved	0	Reads return 0. Writes have no effect.
16	BUF_INIT_ACTIVE		ADC Results Memory Auto-initialization Status. Any operation mode read/write:
		0	ADC Results Memory is currently not being initialized, and the ADC is available. If this bit is read as '0' after triggering an auto-initialization of the ADC results memory, then the ADC results memory has been completely initialized to zeros. For devices requiring parity checking on the ADC results memory, the parity bit in the results memory will also be initialized according to the parity polarity. The parity polarity as well as the auto-initialization process is controlled by the System module. Please refer to Chapter 2 for more details.
		1	ADC results memory is being initialized, and the ADC is not available for conversion.
15-3	Reserved	0	Reads return 0. Writes have no effect.
2-0	BNDEND		Buffer Boundary End. These bits specify the total number of memory buffers available for storing the ADC conversion results. These bits should be programmed to match the number of ADC conversion result buffers required to be used for the application. Any operation mode read/write:
		0	16 words available for storing ADC conversion results.
		1h	32 words available for storing ADC conversion results.
		2h	64 words available for storing ADC conversion results. This is the maximum configuration allowed since the device supports 64 buffers each for ADC1 as well as ADC2.
		4h-7h	Reserved. These combinations must not be used.

Reserved		EV_ACQ	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-31. ADC Event Group Sampling Time Configuration Register (ADEVSAMP) Field Descriptions

Bit	Field	Value	Description
31-12	Reserved	0	Reads return 0. Writes have no effect.
11-0	EV_ACQ		Event Group Acquisition Time. These bits define the sampling window (SW) for the Event Group conversions. SW = EV_ACQ + 2 in terms of ADCLK cycles. There are two factors that determine the minimum sampling window value required: First, the ADC module design requires that SW >= 3 ADCLK cycles. Second, the ADC input impedance necessitates a certain minimum sampling time. This needs to be assured by configuring the EV_ACQ value properly considering the frequency of the ADCLK signal. Refer to the device datasheet to determine the minimum sampling time for this device.

22.3.26 ADC Group1 Sampling Time Configuration Register (ADG1SAMP)

ADC Group1 Sampling Time Configuration Register (ADG1SAMP) is shown in Figure 22-48 and described in Table 22-32.

Figure 22-48. ADC Group1 Sampling Time Configuration Register (ADG1SAMP) [offset = 64h]

LEGEND: R/W = Read/Write; R = Read only; W1C = Write 1 to clear; -*n* = value after reset

Table 22-34. ADC Event Group Status Register (ADEVSR) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reads return 0. Writes have no effect.
3	EV_MEM_EMPTY		Event Group Results Memory Empty. This bit can be effectively used only when the conversion results are read out of the Event Group results memory in the "read from FIFO" mode.
			Any operation mode read:
		0	The Event Group results memory has valid conversion results.
		1	The Event Group results memory is empty, or does not contain any unread conversion results.
2	EV_BUSY		Event Group Conversion Busy.
			Any operation mode read:
		0	Event Group conversions are neither in progress nor frozen.
		1	Event Group conversions are either in progress, or are frozen for servicing some other group. This bit will always be set when the Event Group is configured to be in the continuous conversion mode.
1	EV_STOP		Event Group Conversion Stopped.
			Any operation mode read:
		0	Event Group conversions are not currently frozen.
		1	Event Group conversions are currently frozen.
0	EV_END		Event Group Conversions Ended.
			Any operation mode read:
		0	Event Group conversions have either not been started or have not yet completed since the last time this status bit was cleared.
		1	The conversion for all the channels selected in the Event Group has completed. This bit can be cleared under the following conditions: • By reading a conversion result from the Event Group results memory in the "read from FIFO" mode. • By writing a new value to the Event Group channel select register (ADEVSEL). • By writing a 1 to this bit. • By disabling the ADC module by clearing the ADC_EN bit in the ADC operating mode control register (ADOPMODECR).

22.3.31 ADC Event Group Channel Select Register (ADEVSEL)

ADC Event Group Channel Select Register (ADEVSEL) is shown in Figure 22-53 and described in Table 22-37.

NOTE: Clearing ADEVSEL During a Conversion

Writing 0x0000 to ADEVSEL stops the Event Group conversions. This does not cause the ADC Event Group Results Memory pointer or the Event Group Threshold Register to be reset.

NOTE: Writing A Non-Zero Value To ADEVSEL During a Conversion

Writing a new value to ADEVSEL while a Channel in Event Group is being converted results in a new conversion sequence starting immediately with the highest priority channel in the new ADEVSEL selection. This also causes the ADC Event Group Results Memory pointer to be reset so that the memory allocated for storing the Event Group conversion results gets overwritten. Care should be taken to re-program the corresponding Interrupt Threshold Counter or DMA Threshold Counter again so that correct number of conversions happen before a Threshold interrupt or Block DMA request is generated.

ADC1 supports up to 32 channels and ADC2 supports up to 25 channels on the microcontroller.

Figure 22-53. ADC Event Group Channel Select Register (ADEVSEL) [offset = 78h]

22.3.32 ADC Group1 Channel Select Register (ADG1SEL)

ADC Group1 Channel Select Register (ADG1SEL) is shown in Figure 22-54 and described in Table 22-38.

NOTE: Clearing ADG1SEL During a Conversion

Writing 0x0000 to ADG1SEL stops the Group1 conversions. This does not cause the ADC Group1 Results Memory pointer or the Group1 Threshold Register to be reset.

NOTE: Writing A Non-Zero Value To ADG1SEL During a Conversion

Writing a new value to ADG1SEL while a Channel in Group1 is being converted results in a new conversion sequence starting immediately with the highest priority channel in the new ADG1SEL selection. This also causes the ADC Group1 Results Memory pointer to be reset so that the memory allocated for storing the Group1 conversion results gets overwritten. Care should be taken to re-program the corresponding Interrupt Threshold Counter or DMA Threshold Counter again so that correct number of conversions happen before a Threshold interrupt or Block DMA request is generated.

ADC1 supports up to 32 channels and ADC2 supports up to 25 channels on the microcontroller.

22.3.33 ADC Group2 Channel Select Register (ADG2SEL)

ADC Group2 Channel Select Register (ADG2SEL) is shown in Figure 22-55 and described in Table 22-39.

NOTE: Clearing ADG2SEL During a Conversion

Writing 0x0000 to ADG2SEL stops the Group2 conversions. This does not cause the ADC Group2 Results Memory pointer or the Group2 Threshold Register to be reset.

NOTE: Writing A Non-Zero Value To ADG2SEL During a Conversion

Writing a new value to ADG2SEL while a Channel in Group2 is being converted results in a new conversion sequence starting immediately with the highest priority channel in the new ADG2SEL selection. This also causes the ADC Group2 Results Memory pointer to be reset so that the memory allocated for storing the Group2 conversion results gets overwritten. Care should be taken to re-program the corresponding Interrupt Threshold Counter or DMA Threshold Counter again so that correct number of conversions happen before a Threshold interrupt or Block DMA request is generated.

ADC1 supports up to 32 channels and ADC2 supports up to 25 channels on the microcontroller.

R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-40. ADC Calibration and Error Offset Correction Register (ADCALR) Field Descriptions

Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
ADCALR		ADC Calibration Result and Offset Error Correction Value. The ADC module writes the results of the calibration conversions to this register. The application is required to use these conversion results and determine the ADC offset error. The application can then compute the correction for the offset error and this correction value needs to be written back to the ADCALR register in the 2's complement form. During normal conversion (when calibration is disabled), the ADCALR register contents are automatically added to each digital output from the ADC core before it is stored in the ADC results memory. For more details on error calibration, refer to Section 22.2.6.1.

22.3.35 ADC State Machine Status Register (ADSMSTATE)

Figure 22-58 and Table 22-41 describe the ADSMSTATE register.

Figure 22-58. ADC State Machine Status Register (ADSMSTATE) [offset = 88h]

Reserved		SMSTATE	
R-0		R-0	

LEGEND: R = Read only; -*n* = value after reset

Table 22-41. ADC State Machine Status Register (ADSMSTATE) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	SMSTATE		ADC State Machine Current State. These bits reflect the current state of the state machine and are reserved for use by TI for debug purposes.

Copyright © 2018, Texas Instruments Incorporated

22.3.36 ADC Channel Last Conversion Value Register (ADLASTCONV)

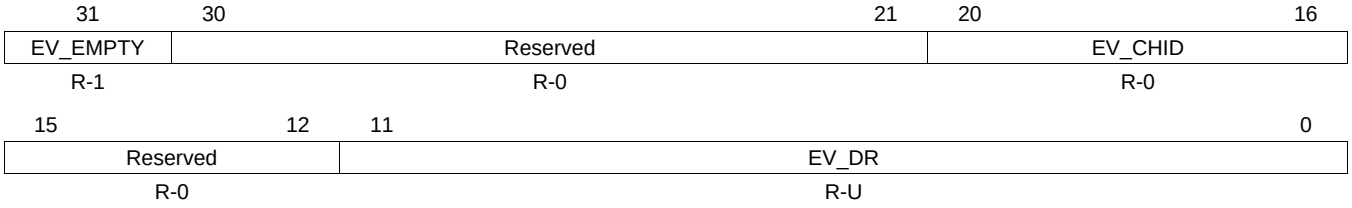
ADC Channel Last Conversion Value Register (ADLASTCONV) is shown in Figure 22-59 and described in Table 22-42.

Figure 22-59. ADC Channel Last Conversion Value Register (ADLASTCONV) [offset = 8Ch]

31	24	23	0
Reserved		LAST_CONV	
R-0		R-U	

LEGEND: R = Read only; -*n* = value after reset; U = value after reset is unknown

Table 22-42. ADC Channel Last Conversion Value Register (ADLASTCONV) Field Descriptions



Bit	Field	Value	Description
31-24	Reserved	0	Reads return 0. Writes have no effect.
23-0	LAST_CONV		ADC Input Channel's Last Converted Value. This register indicates whether the last converted value for a particular input channel was lower or higher than the mid-point of the reference voltage. In other words, this register acts as a digital input register and can be read by the application to determine the digital level at the input pins. This data is only valid for an input channel if it has been converted at least once. Any operation mode read for each bit of this register:
		0	A level lower than the midpoint reference voltage was measured at the last conversion for this channel.
		1	A level higher than or equal to the midpoint reference voltage was measured at the last conversion for this channel.

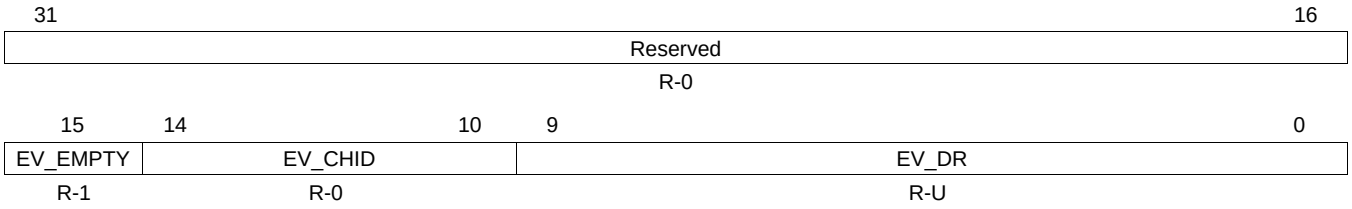
22.3.37 ADC Event Group Results' FIFO Register (ADEVBUFFER)



ADC Event Group Results' FIFO Register (ADEVBUFFER) is shown in Figure 22-60 and Figure 22-61, and described in Table 22-43. As shown, the format of the data read from the ADEVBUFFER locations is different based on whether the ADC module is configured to be a 12-bit or a 10-bit ADC module.

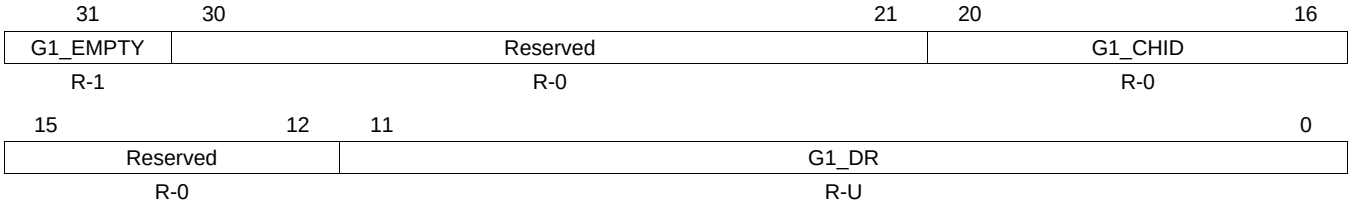
Figure 22-60. 12-bit ADC Event Group Results' FIFO Register (ADEVBUFFER) [offset = 90h-AFh]

LEGEND: R = Read only; -*n* = value after reset; U = value after reset is unknown

Figure 22-61. 10-bit ADC Event Group Results' FIFO Register (ADEVBUFFER) [offset = 90h-AFh]

LEGEND: R = Read only; -*n* = value after reset; U = value after reset is unknown

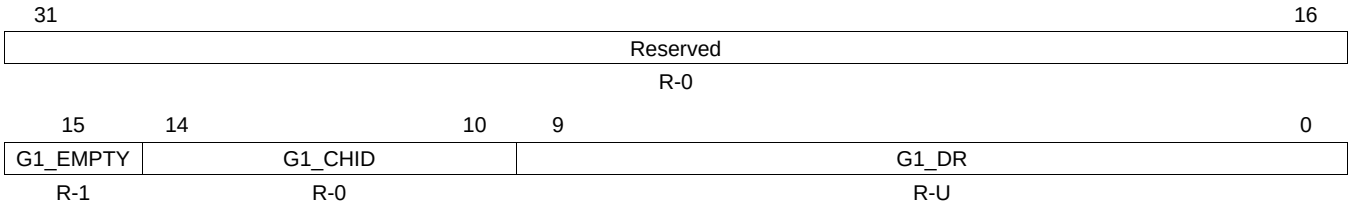
Table 22-43. ADC Event Group Results' FIFO Register (ADEVBUFFER) Field Descriptions



Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
EV_EMPTY		Event Group FIFO Empty. This bit is applicable only when the "read from FIFO" mode is used for reading the Event Group conversion results.
		Any operation mode read:
	0	The data in the EV_DR field of this buffer is valid.
	1	The data in the EV_DR field of this buffer is not valid and there are no valid data in the Event Group results memory.
EV_CHID		Event Group Channel Id. These bits are also applicable only when the "read from FIFO" mode is used for reading the Event Group conversion results.
		Any operation mode read:
	0	The conversion result in the EV_DR field of this buffer is from the ADC input channel 0, or the channel id mode is disabled in the Event Group mode control register (ADEVMODECR).
	1h-1Fh	The conversion result in the EV_DR field of this buffer is from the ADC input channel number denoted by the EV_CHID field.
EV_DR		Event Group Digital Conversion Result.
		The Event Group results' FIFO location is aliased eight times, so that any word-aligned read from the address range 90h to AFh results in one conversion result to be read from the Event Group results' memory. This allows the ARM LDMIA instruction to read out up to 8 conversion results from the Event Group results' memory with just one instruction.

Copyright © 2018, Texas Instruments Incorporated

22.3.38 ADC Group1 Results FIFO Register (ADG1BUFFER)



ADC Group1 Results FIFO Register (ADG1BUFFER) is shown in Figure 22-62 and Figure 22-63, described in Table 22-44. As shown, the format of the data read from the ADG1BUFFER locations is different based on whether the ADC module is configured to be a 12-bit or a 10-bit ADC module.

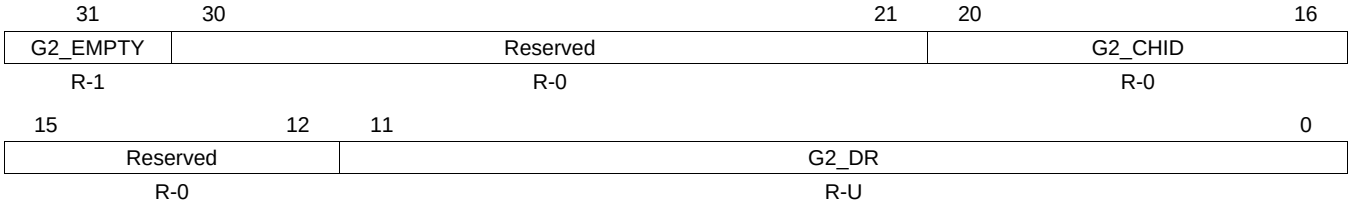
Figure 22-62. 12-bit ADC Group1 Results FIFO Register (ADG1BUFFER) [offset = B0h-CFh]

LEGEND: R = Read only; -*n* = value after reset; U = value after reset is unknown

Figure 22-63. 10-bit ADC Group1 Results' FIFO Register (ADG1BUFFER) [offset = B0h-CFh]

LEGEND: R = Read only; -*n* = value after reset; U = value after reset is unknown

Table 22-44. ADC Group1 Results FIFO Register (ADG1BUFFER) Field Descriptions



Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
G1_EMPTY		Group1 FIFO Empty. This bit is applicable only when the "read from FIFO" mode is used for reading the Group1 conversion results.
		Any operation mode read:
	0	The data in the G1_DR field of this buffer is valid.
	1	The data in the G1_DR field of this buffer is not valid and there are no valid data in the Group1 results memory.
G1_CHID		Group1 Channel Id. These bits are also applicable only when the "read from FIFO" mode is used for reading the Group1 conversion results.
		Any operation mode read:
	0	The conversion result in the G1_DR field of this buffer is from the ADC input channel 0, or the channel id mode is disabled in the Group1 mode control register (ADG1MODECR).
	1h-1Fh	The conversion result in the G1_DR field of this buffer is from the ADC input channel number denoted by the G1_CHID field.
G1_DR		Group1 Digital Conversion Result.
		The Group1 results' FIFO location is aliased eight times, so that any word-aligned read from the address range B0h to CFh results in one conversion result to be read from the Group1 results' memory. This allows the ARM LDMIA instruction to read out up to 8 conversion results from the Group1 results' memory with just one instruction.

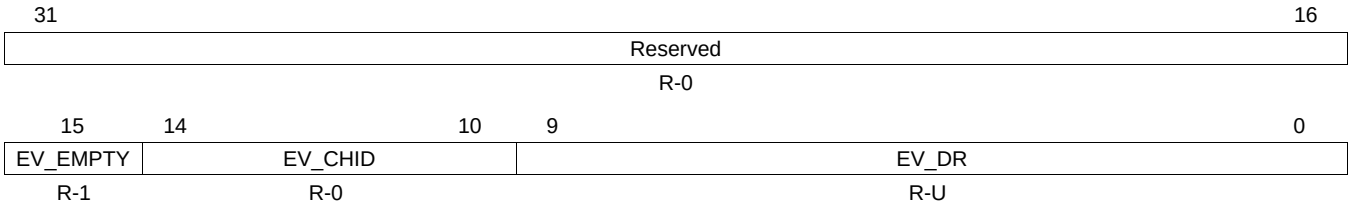
22.3.40 ADC Event Group Results Emulation FIFO Register (ADEVEMUBUFFER)

ADC Event Group Results Emulation FIFO Register (ADEVEMUBUFFER) is shown in Figure 22-66 and Figure 22-67, and described in Table 22-46. As shown, the format of the data read from the ADEVEMUBUFFER locations is different based on whether the ADC module is configured to be a 12-bit or a 10-bit ADC module.



A read from this location also gives out one conversion result from the Event Group results' memory along with the EV_EMPTY status bit and the optional channel id. However, this read will not affect any of the status flags in the Event Group interrupt flag register or the Event Group status register. This register is useful for debuggers.

Figure 22-66. 12-bit ADC Event Group Results Emulation FIFO Register (ADEVEMUBUFFER) [offset = F0h]

LEGEND: R = Read only; -*n* = value after reset; U = value after reset is unknown

Figure 22-67. 10-bit ADC Event Group Results Emulation FIFO Register (ADEVEMUBUFFER) [offset = F0h]

LEGEND: R = Read only; -*n* = value after reset; U = value after reset is unknown

Table 22-46. ADC Event Group Results Emulation FIFO Register (ADEVEMUBUFFER) Field Descriptions

Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
EV_EMPTY		Event Group FIFO Empty. This bit is applicable only when the "read from FIFO" mode is used for reading the Event Group conversion results.
		Any operation mode read:
	0	The data in the EV_DR field of this buffer is valid.
	1	The data in the EV_DR field of this buffer is not valid and there are no valid data in the Event Group results memory.
EV_CHID		Event Group Channel Id. These bits are also applicable only when the "read from FIFO" mode is used for reading the Event Group conversion results.
		Any operation mode read:
	0	The conversion result in the EV_DR field of this buffer is from the ADC input channel 0, or the channel id mode is disabled in the Event Group operating mode control register (ADEVMODECR).
	1h-1Fh	The conversion result in the EV_DR field of this buffer is from the ADC input channel number denoted by the EV_CHID field.
EV_DR		Event Group Digital Conversion Result.
		These bits contain the digital result output from the Event Group FIFO buffer. The result can be presented in an 8-bit, 10-bit, or 12-bit format for a 12-bit ADC module, or in an 8-bit or 10-bit format for a 10-bit ADC module. The conversion result data is automatically shifted right by the appropriate number of bits when using a reduced-size data format with the upper bits reading as zeros.

Table 22-47. ADC Group1 Results Emulation FIFO Register (ADG1EMUBUFFER) Field Descriptions

Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
G1_EMPTY		Group1 FIFO Empty. This bit is applicable only when the "read from FIFO" mode is used for reading the Group1 conversion results.
		Any operation mode read:
	0	The data in the G1_DR field of this buffer is valid.
	1	The data in the G1_DR field of this buffer is not valid and there are no valid data in the Group1 results memory.
G1_CHID		Group1 Channel Id. These bits are also applicable only when the "read from FIFO" mode is used for reading the Group1 conversion results.
		Any operation mode read:
	0	The conversion result in the G1_DR field of this buffer is from the ADC input channel 0, or the channel id mode is disabled in the Group1 operating mode control register (ADG1MODECR).
	1h-1Fh	The conversion result in the G1_DR field of this buffer is from the ADC input channel number denoted by the G1_CHID field.
G1_DR		Group1 Digital Conversion Result.
		These bits contain the digital result output from the Group 1 FIFO buffer. The result can be presented in an 8-bit, 10-bit, or 12-bit format for a 12-bit ADC module, or in an 8-bit or 10-bit format for a 10-bit ADC module. The conversion result data is automatically shifted right by the appropriate number of bits when using a reduced-size data format with the upper bits reading as zeros.

22.3.54 ADC Magnitude Compare Interrupt Control Registers (ADMAGINTxCR)

ADC Magnitude Compare Interrupt Control Registers (ADMAGINTxCR) are shown in Figure 22-83 and Figure 22-84, and described in Table 22-60. As shown, the format of the ADMAGINTxCR is different based on whether the ADC module is configured to be a 12-bit or a 10-bit ADC module. The ADC module supports up to three magnitude compare interrupts. These registers are at offset addresses 128h, 130h, and 138h.

Table 22-60. ADC Magnitude Compare Interrupt Control Registers (ADMAGINTxCR) Field Descriptions

Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
MAG_CHIDx		These bits specify the channel number from 0 to 31 for which the conversion result needs to be monitored by the ADC.
MAG_THRx		These bits specify the 12-bit or 10-bit compare value that the ADC will use for the comparison with the MAG_CHIDx channel's conversion result.
COMP_CHIDx		These bits specify the channel number from 0 to 31 whose last conversion result is compared with the MAG_CHIDx channel's conversion result.
CHN_THR_COMPx		Channel OR Threshold comparison. Any operation mode read/write: 0 The ADC module will compare the MAG_CHIDx channel's conversion result with the fixed threshold value specified by the MAG_THRx field 1 The ADC module will compare the MAG_CHIDx channel's conversion result with the last conversion result for the COMP_CHIDx channel. Both the MAG_CHIDx and the COMP_CHIDx channel must have been converted at least once for the ADC to perform the comparison.
CMP_GE_LTx		"Greater than or equal to" OR "Less than" comparison operator. Any operation mode read/write: 0 The ADC module will check if the conversion result is lower than the reference value (fixed threshold or COMP_CHIDx conversion result). 1 The ADC module will check if the conversion result is greater than or equal to the reference value (fixed threshold or COMP_CHIDx conversion result).

22.3.55 ADC Magnitude Compare Interruptx Mask Register (ADMAGINTxMASK)

ADC Magnitude Compare Interruptx Mask Register (ADMAGINTxMASK) is shown in Figure 22-85and Figure 22-86, and described in Table 22-61. As shown, the format of the ADMAGINTxMASK is different based on whether the ADC module is configured to be a 12-bit or a 10-bit ADC module. There are three mask registers for the three magnitude compare interrupts. These registers are at offset addresses 12Ch, 134h, and 13Ch.

Figure 22-85. 12-bit ADC Magnitude Compare Mask Register (ADMAGINTxMASK) [offset = 12Ch-13Ch]

31	12	11	0
Reserved		MAG_INTx_MASK	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Figure 22-86. 10-bit ADC Magnitude Compare Mask Register (ADMAGINTxMASK) [offset = 12Ch-13Ch]

31	10	9	0
Reserved		MAG_INTx_MASK	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-61. ADC Magnitude Compare Interruptx Mask Register (ADMAGINTxMASK) Field Descriptions

Field	Value	Description
Reserved	0	Reads return 0. Writes have no effect.
MAG_INTx_MASK		These bits specify the mask for the comparison in order to generate the magnitude compare interrupt # x.
		Any operation mode read/write:
	0	The ADC module will not mask the corresponding bit for the comparison.
	1	The ADC module will mask the corresponding bit for the comparison.

22.3.56 ADC Magnitude Compare Interrupt Enable Set Register (ADMAGINTENASET)

ADC Magnitude Compare Interrupt Enable Set Register (ADMAGINTENASET) is shown in Figure 22-87 and described in Table 22-62.

Figure 22-87. ADC Magnitude Compare Interrupt Enable Set Register (ADMAGINTENASET) [offset = 158h]

31	3	2	0
Reserved		MAG_INT_ENA_SET	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-62. ADC Magnitude Compare Interrupt Enable Set Register (ADMAGINTENASET) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reads return 0. Writes have no effect.
2-0	MAG_INT_ENA_SET		Each of these three bits, when set, enable the corresponding magnitude compare interrupt.
			Any operation mode read/write for each bit:
		0	The enable status of the corresponding magnitude compare interrupt is left unchanged.
		1	The corresponding magnitude compare interrupt is enabled.

22.3.57 ADC Magnitude Compare Interrupt Enable Clear Register (ADMAGINTENACLR)

ADC Magnitude Compare Interrupt Enable Clear Register (ADMAGINTENACLR) is shown in Figure 22-88 and described in Table 22-63.

Figure 22-88. ADC Magnitude Compare Interrupt Enable Clear Register (ADMAGINTENACLR) [offset = 15Ch]

31	3	2	0
Reserved		MAG_INT_ENA_CLR	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-63. ADC Magnitude Compare Interrupt Enable Clear Register (ADMAGINTENACLR) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reads return 0. Writes have no effect.
2-0	MAG_INT_ENA_CLR		Each of these three bits, when set, enable the corresponding magnitude compare interrupt.
			Any operation mode read/write for each bit:
		0	The enable status of the corresponding magnitude compare interrupt is left unchanged.
		1	The corresponding magnitude compare interrupt is disabled.

22.3.58 ADC Magnitude Compare Interrupt Flag Register (ADMAGINTFLG)

ADC Magnitude Compare Interrupt Flag Register (ADMAGINTFLG) is shown in Figure 22-89 and described in Table 22-64.

Figure 22-89. ADC Magnitude Compare Interrupt Flag Register (ADMAGINTFLG) [offset = 160h]

31	3	2	0
Reserved		MAG_INT_FLG	
R-0		R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-64. ADC Magnitude Compare Interrupt Flag Register (ADMAGINTFLG) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reads return 0. Writes have no effect.
2-0	MAG_INT_FLG		Magnitude Compare Interrupt Flags. These bits can be polled by the application to determine if the magnitude compares have been evaluated as true. When a magnitude compare interrupt flag is set, the corresponding magnitude compare interrupt will be generated if enabled. Any operation mode, for each bit:
		0	Read: The condition for the corresponding magnitude threshold interrupt was false. Write: The corresponding flag is left unchanged.
		1	Read: The condition for the corresponding magnitude threshold interrupt was true. Write: The corresponding flag is cleared. The flag can also be cleared by reading from the magnitude compare interrupt offset register.

22.3.59 ADC Magnitude Compare Interrupt Offset Register (ADMAGINTOFF)

ADC Magnitude Compare Interrupt Offset Register (ADMAGINTOFF) is shown in Figure 22-90 and described in Table 22-65.

Figure 22-90. ADC Magnitude Compare Interrupt Offset Register (ADMAGINTOFF) [offset = 164h]

31	4	3	0
Reserved		MAG_INT_OFF	
R-0		RC-0	

LEGEND: R = Read only; RC = Clear field after read; -*n* = value after reset

Table 22-65. ADC Magnitude Compare Interrupt Offset Register (ADMAGINTOFF) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	MAG_INT_OFF		Magnitude Compare Interrupt Offset. This field indexes the currently highest-priority magnitude compare interrupt. Interrupt 1 has the highest priority and interrupt 3 has the lowest priority among the magnitude compare interrupts. Writes to these bits have no effect. A read from this register clears this register as well as the corresponding magnitude compare interrupt flag in the ADMAGINTFLG register. However, a read from this register in emulation mode does not affect this register or the interrupt status flags. Any operation mode read:
		0	No magnitude compare interrupt is pending.
		1h	Magnitude compare interrupt # 1 is pending.
		2h	Magnitude compare interrupt # 2 is pending.
		3h	Magnitude compare interrupt # 3 is pending.
		4h-Fh	Reserved.

22.3.60 ADC Event Group FIFO Reset Control Register (ADEVFIFORESETCR)

ADC Event Group FIFO Reset Control Register (ADEVFIFORESETCR) is shown in Figure 22-91 and described in Table 22-66.

Figure 22-91. ADC Event Group FIFO Reset Control Register (ADEVFIFORESETCR) [offset = 168h]

31	1	0
Reserved		EV_FIFO_RESET
R-0		R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 22-66. ADC Event Group FIFO Reset Control Register (ADEVFIFORESETCR) Field Descriptions

Bit	Field	Value	Description
31-1	Reserved	0	Reads return 0. Writes have no effect.
0	EV_FIFO_RESET		ADC Event Group FIFO Reset. The application can set this bit in case of an overrun condition. This allows the ADC module to overwrite the contents of the Event Group results memory starting from the first location. When this bit is set to 1, the ADC module resets its internal Event Group results memory pointers. Then this bit automatically gets cleared, so that the ADC module allows the Event Group results memory to be overwritten only once each time this bit is set to 1. As a result, the EV_FIFO_RESET bit will always be read as a 0. The EV_FIFO_RESET bit will only have the desired effect when the Event Group results memory is in an overrun condition. It must be used when the data already available in the results memory can be discarded. If the application needs the Event Group memory to always be overwritten with the latest available conversion results, then the OVR_EV_RAM_IGN bit in the Event Group operating mode control register (ADEVMODECR) needs to be set to 1.

22.3.61 ADC Group1 FIFO Reset Control Register (ADG1FIFORESETCR)

ADC Group1 FIFO Reset Control Register (ADG1FIFORESETCR) is shown in Figure 22-92 and described in Table 22-67.

Figure 22-92. ADC Group1 FIFO Reset Control Register (ADG1FIFORESETCR) [offset = 16Ch]

Table 22-72. ADC Parity Control Register (ADPARCR) Field Descriptions

Bit	Field	Value	Description
31-9	Reserved	0	Reads return 0. Writes have no effect.
8	TEST		This bit maps the parity bits into the ADC results' RAM frame so that the application can access them.
			Any operation mode read, privileged mode write:
		0	The parity bits are not memory-mapped.
		1	The parity bits are memory-mapped.
7-4	Reserved	0	Reads return 0. Writes have no effect.
3-0	PARITY_ENA		Enable parity checking. These bits enable the parity check on read operations and the parity calculation on write operations to the ADC results memory.
			If parity checking is enabled and a parity error is detected the ADC module sends a parity error signal to the System module.
			Any operation mode read, privileged mode write:
		5h	Parity check is disabled.
		All other values	Parity check is enabled.

Copyright © 2018, Texas Instruments Incorporated

22.3.67 ADC Parity Error Address Register (ADPARADDR)

ADC Parity Error Address Register (ADPARADDR) is shown inFigure 22-98 and described in Table 22-73.

High-End Timer (N2HET) Module

This chapter provides a general description of the High-End Timer (N2HET). The N2HET is a software-controlled timer with a dedicated specialized timer micromachine and a set of 30 instructions. The N2HET micromachine is connected to a port of up to 32 input/output (I/O) pins.

NOTE: This chapter describes a superset implementation of the N2HET module that includes features and functionality that require DMA. Since not all devices have DMA capability, consult your device-specific datasheet to determine the applicability of these features and functions to your device being used.

23.1 Overview

The N2HET is a fifth-generation Texas Instruments (TI) advanced intelligent timer module. It provides an enhanced feature set compared to previous generations.

This timer module provides sophisticated timing functions for real-time applications such as engine management or motor control. The high resolution hardware channels allow greater accuracy for widely used timing functions such as period and pulse measurements, output compare, and PWMs.

The reduced instruction set, based mostly on very simple, but comprehensive instructions, improves the definition and development cycle time of an application and its derivatives. The N2HET breakpoint feature, combined with various stop capabilities, makes the N2HET software application easy to debug.

23.1.1 Features

- Programmable timer for input and output timing functions
- Reduced instruction set (30 instructions) for dedicated time and angle functions
- Up to maximum of 128 96-bit words of instruction RAM protected by parity. Check your datasheet for the actual number of words implemented.
- User defined configuration of 25-bit virtual counters for timer, event counters and angle counters
- 7-bit hardware counters for each pin allow up to 32-bit resolution in conjunction with the 25-bit virtual counters
- Up to 32 pins usable for input signal measurements or output signal generation
- Programmable suppression filter for each input pin with adjustable suppression window
- Low CPU overhead and interrupt load
- Efficient data transfer to or from the CPU memory with dedicated High-End-Timer Transfer Unit (HTU) or DMA
- Diagnostic capabilities with different loopback mechanisms and pin status readback functionality
- Hardware Angle Generator (HWAG)

23.1.2 Major Advantages

In addition to classic time functions such as input capture or multiple PWMs, higher-level time functions can be easily implemented in the timer program main loop. Higher-level time functions include angle driven wave forms, angle- and time-driven pulses, and input pulse width modulation (PWM) duty cycle measurement.

Because of these high-level functions, data exchanges with the CPU are limited to the fundamental parameters of the application (periods, pulse widths, angle values, etc.); and the real-time constraints for parameter communication are dramatically minimized; for example, few interrupts are required and asynchronous parameter updates are allowed.

The reduced instruction set and simple execution flow control make it simple and easy to develop and modify programs. Simple algorithms can embed the entire flow control inside the N2HET program itself. More complex algorithms can take advantage of the CPU access to the N2HET RAM. With this, the CPU program can make calculations and can modify the timer program flow by changing the data and control fields of the N2HET RAM. CPU access to the N2HET RAM also improves the debug and development of timer programs. The CPU program can stop the N2HET and view the contents of the program, control, and data fields that reside in the N2HET RAM.

Finally, the modular structure provides maximum flexibility to address a wide range of applications. The timer resolution can be selected from two cascaded prescalers to adjust the loop resolution and HR clocks. The 32 I/O pins can provide any combination of input, period or pulse capture, and output compare, including high resolution for each channel.

23.1.3 Block Diagram

The N2HET module (see Figure 23-1) comprises four separate components:

- Host interface
- N2HET RAM
- Specialized timer micromachine
- I/O control (the N2HET is attached to an I/O port of up to 32 pins)

Figure 23-1. N2HET Block Diagram

23.1.4 Timer Module Structure and Execution

The timer consists of a specialized micromachine that operates a reduced instruction set. Two 25-bit registers and three 32-bit registers are available to manipulate information such as time, event counts, and angle values. System performance is improved by a wide instruction format (96 bits) that allows the N2HET to fetch the instructional operation code and data in one system cycle, thus increasing the speed at which data can be processed. The typical operations performed in the ALU are additions (count), compares, and magnitude compares (higher or same).

Each instruction is made up of a 32-bit program field, a 32-bit control field and a 32-bit data field. The N2HET execution unit fetches the complete 96-bit instruction in one cycle and executes it. All instructions include a 9-bit field for specifying the address of the next instruction to be executed. Some instructions also include a 9-bit conditional address, which is used as the next address whenever a particular condition is true. This makes controlling the flow of an N2HET program inexpensive; in many cases a separate branch instruction is not required.

The interface to the host CPU is based on both communication memory and control registers. The communication memory includes timer instructions (program and data). This memory is typically initialized by the CPU or DMA after reset before the timer starts execution. Once the timer program is loaded into the memory, the CPU starts the timer execution, and typically data parameters are then read or written into the timer memory. The control registers include bits for selecting timer clock, configuring I/O pins, and controlling the timer module.

The programmer implements timer functions by combining instructions in specific sequences. For instance, a single count (CNT) instruction implements a timer. A simple PWM generator can be implemented with a two instruction sequence: CNT and compare (ECMP or MCMP). A complex time function may include many instructions in the sequence. The total timer program is a set of instructions executed sequentially, one after the other. Reaching the end, the program must roll to the first instruction so that it behaves as a loop. The time for a loop to execute is referred to as a *loop resolution clock cycle* or *loop resolution period (LRP).* When the N2HET rolls over to the first instruction, the timer waits for the loop resolution clock to restart the execution of the loop to ensure that only one loop is executed for each loop resolution clock.

The longest path through an N2HET program must be completed within the loop resolution clock (LRP). Otherwise, the program will execute unpredictably because some instructions will not be executed each time through the loop. This effect creates a strong link between the accuracy of the timer functions and the number of functions (the number of instructions) the timer can perform. High resolution (HR) hardware timer extensions are available for each of the N2HET pins to help overcome this limitation.

The high resolution hardware timers operate from the *high resolution clock*, which may be configured for frequency multiples between 2 and 128 times the loop resolution clock frequency. This extending the resolution of timer events and measurements well beyond what is possible with only loop resolution instructions.

Most of the commonly used N2HET instructions can operate either at loop resolution or high resolution; with the restriction that for each pin at most one high resolution instruction can be executed per loop resolution period.

Certain instructions (MOV32, ADM32, ...) can modify the data fields of other instructions. This feature enables the N2HET program to implement double buffering on capture and compare functions. For example, an ECMP compare instruction can be followed by a MOV32 instruction that is conditionally executed when the ECMP instruction matches. The host CPU can update the next compare value by writing asynchronously to the data field of the MOV32 instruction instead of writing directly to the data field of the ECMP instruction. The copy from the buffer (MOV32 data field) to the compare register (ECMP data field) will occur when the MOV32 instruction is actually executed which occurs after the ECMP instruction matches its current compare value. This is the same behavior as one would expect from a double buffered hardware compare register.

Copyright © 2018, Texas Instruments Incorporated

Other instructions (MOV64, RADM64) can modify both the control and data fields of other instructions. This allows the N2HET to implement toggle functionality. For example, an ECMP instruction can be followed by a pair of MOV64 instructions. The MOV64 instruction updates the data field of the ECMP instruction to implement the double buffering behavior. But it also updates the control field of the ECMP instruction which allows it to change things like pin action and the conditional address. If one MOV64 instruction configures the ECMP pin action to SET while the second changes it to CLEAR, and the two MOV64 instructions update the conditional address to point to each other, then a single ECMP instruction can be used to toggle a pin each time the compare match occurs.

23.1.5 Performance

Most instructions execute in one cycle, but a few take two or three cycles.

The N2HET can generate many complex output waveforms without CPU interrupts. Where special algorithms are needed following a specific event (for example, missing teeth or a short/long input signal), a minimal number of interrupts to the CPU are needed freeing the CPU for other tasks.

23.1.6 N2HET Compared to NHET

N2HET enhancements from NHET include:

- Eight new instructions: ADD, ADC, SUB, SBB, AND, OR, XOR, RCNT
- Full set of ALU flags Carry (C), Negative (N), Zero (Z), Overflow (V)
- Branch instruction (BR) extended to support signed and unsigned arithmetic comparison conditions
- Two additional 32-bit temporary working registers R, S.
- New HETAND register for AND-Sharing of High Resolution structure between pairs of pins
- Improved high resolution PCNT instruction

23.1.7 NHET and N2HET Compared to HET

Compared to the HET module, the N2HET contains all of the enhancements described in Section 23.1.6 plus the following additional enhancements:

- New Interrupt Enable Set and Clear registers
- Capability to generate requests to the DMA module or the HET Transfer Unit (HTU) including new Request Enable Set and Clear registers
- N2HET RAM parity error detection
- Suppression filters for each of the 32 I/O channel and control register to configure the limiting frequency and counter clock
- Enhanced edge detection hardware that does not rely on the previous bit field in the control word of the N2HET instruction.
- The next, conditional and remote addresses are extended from 8 to 9 bits
- The loop resolution data fields are extended from 20 to 25 bits
- The high resolution data fields are extended from 5 to 7 bits
- Instructions with an adequate condition are able to specify the number of the request line, which triggers either the HET Transfer Unit (HTU) or the DMA module
- The CNT instruction provides a bit, which allows to configure either an equal comparison or a greater or equal comparison when comparing the selected register value with the Max-value
- The MOV32 instruction provides a new bit. If set to one the MOV32 will only perform the move, when the Z-flag is set. If set to zero the MOV32 will perform the move whenever it is executed (independent on the state of the Z-flag)
- There is a new instruction WCAPE, which is a combination of a time stamp and an edge counter
- New Open Drain, Pull Disable, and Pull Select registers

Copyright © 2018, Texas Instruments Incorporated

23.1.8 Instructions Features

The N2HET has the following instructions features:

- N2HET uses a RISC-based specialized timer micromachine to carry out a set of 30 instructions
- Instructions are implemented in a Very Long Instruction Word (VLIW) format (96-bits wide)
- The N2HET program execution is self-driven by external or internal events, branching to special routines based on input edges or output compares
- Instructions point to the next instruction executed, eliminating the need for a program counter
- Several instructions can change the program flow based on internal or external conditions

23.1.9 Program Usage

The N2HET instructions/program can be assembled with the N2HET assembler. The assembler generates a C-structure which can be included into the main application program. The application has to copy the content of the structure into the N2HET RAM, set up necessary registers and start the N2HET program execution. In addition to the C-structure, the assembler generates also a header file which makes it easy for the main application to access the different instructions and change for example the duty cycle of a PWM or read out the captured value of a specific signal edge.

23.2 N2HET Functional Description

The N2HET contains RAM into which N2HET code is loaded. The N2HET code is run by the specialized timer micromachine. The host interface and I/O control provide an interface to the CPU and external pins respectively.

23.2.1 Specialized Timer Micromachine

The N2HET has its own instruction set, detailed in Section 23.6.1. The timer micromachine reads each instruction from the N2HET RAM. The program and control fields contain the instructions for how the specialized timer micromachine executes the command. For most instructions, the data field stores the information that needs to be manipulated.

The specialized timer micromachine executes the instructions stored in the N2HET RAM sequentially. The N2HET program execution is self-driven by external or internal events. This means that input edges or output compares may force the program to branch to special routines using a conditional address.

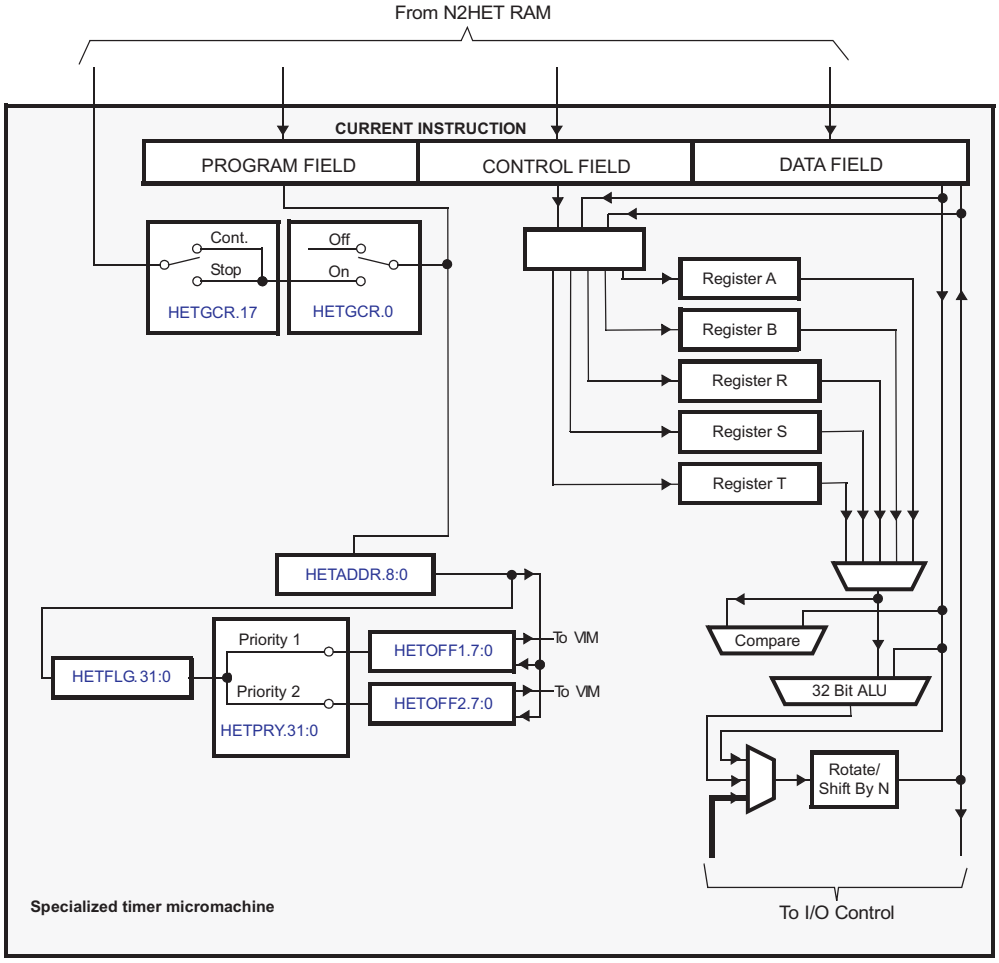

Figure 23-2 shows some of the major operations that the N2HET can carry out, namely compares, captures, angle functions, additions, and shifts. The N2HET contains five registers (A, B, R, S, and T) used to hold compare or counter values and are used by the N2HET instructions. Data may be taken from the registers or the data field for manipulation; likewise, the data may be returned to the registers or the data field.

23.2.1.1 Time Slots and Resolution Loop

Each instruction requires a specific number of cycles or time slots to execute. The resolution specified in the prescaler bitfields determines the timer accuracy. All input captures, event counts, and output compares are executed once in each resolution loop. HR captures and compares are possible (up to N2HET clock accuracy) on the HR I/O pins. For more information about the HR I/O structure, see Section 23.2.5.

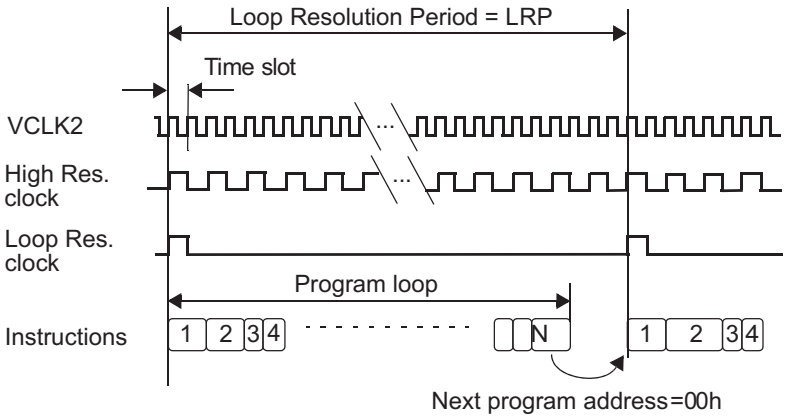
Figure 23-2. Specialized Timer Micromachine

Copyright © 2018, Texas Instruments Incorporated

23.2.1.2 Program Loop Time



The program loop time is the sum of all cycles used for instruction execution. This time may vary from one loop to another if the N2HET program includes conditionally executed instructions.

The timer program restarts on every resolution loop. The start address is fixed at N2HET RAM address 00h. The longest path through a program must fit within one loop resolution period to guarantee complete accuracy.

The last instruction of a program must branch back to the fixed start address (next program address = 00h). When an N2HET program branches back to address 00h before the end of a loop resolution period, the N2HET detects this and pauses instruction execution until the beginning of the next loop resolution period.

The timing diagram in Figure 23-3 illustrates the program flow execution.

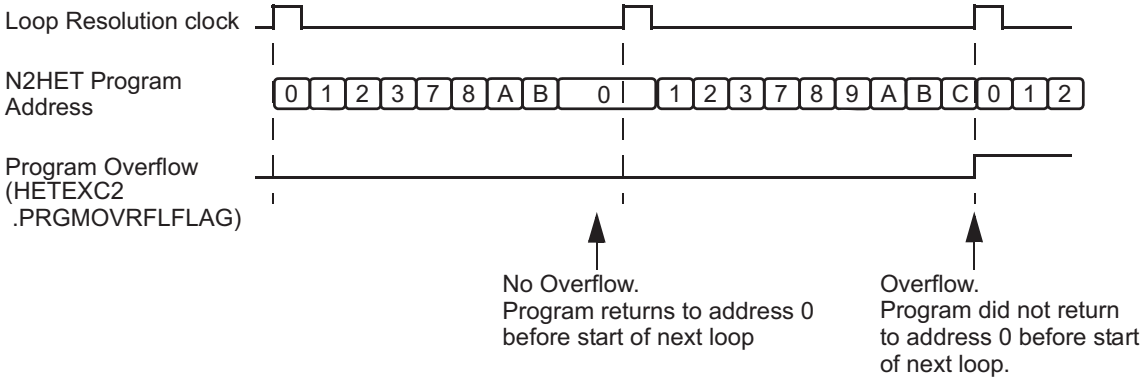
Figure 23-3. Program Flow Timings

23.2.1.3 Instruction Execution Sequence

The execution of a N2HET program begins with the first occurrence of the loop resolution clock, after the N2HET is turned on. At the first and subsequent occurrences of the loop resolution, the instruction at location address 00h is prefetched. The program execution begins at the occurrence of the loop resolution clock and continues executing the instructions until the program branches to 00h location. The instruction is prefetched at location 00h and execution flag is reset. The N2HET pauses instruction execution until the occurrence of the loop resolution clock and resumes normal execution.

N2HET programs must be written so that they complete execution and return to address 00h before the occurrence of the next loop resolution clock. If the N2HET program exceeds this execution time limit, then a program overflow condition occurs as described in Section 23.2.1.4.

23.2.1.4 Program Overflow Condition



If the number of time slots used in a program loop exceeds the number available time slots in one loop resolution, the timer sets the program overflow interrupt flag located in the HETEXC2 register. To maintain synchronization of the I/Os, this condition should never be allowed to occur in a normal operation. The HETEXC2.PRGMOVRFLFLAG flag provides a mechanism for checking that the condition does not occur during the debug and validation phases.

As Figure 23-4 illustrates, when a program overflow occurs, the currently executing N2HET program sequence is interrupted and restarted at N2HETaddress 0 for the beginning of the next loop resolution clock period. Also, HETEXC2.PRGMOVRFLFLAG is set.

If the instruction that caused the overflow (instruction at address 0xC in Figure 23-4) has any pin actions selected, these pin actions will not be performed. However other actions of the instruction including register and RAM updates will still be performed.

Copyright © 2018, Texas Instruments Incorporated

Figure 23-4. Use of the Overflow Interrupt Flag (HETEXC2)

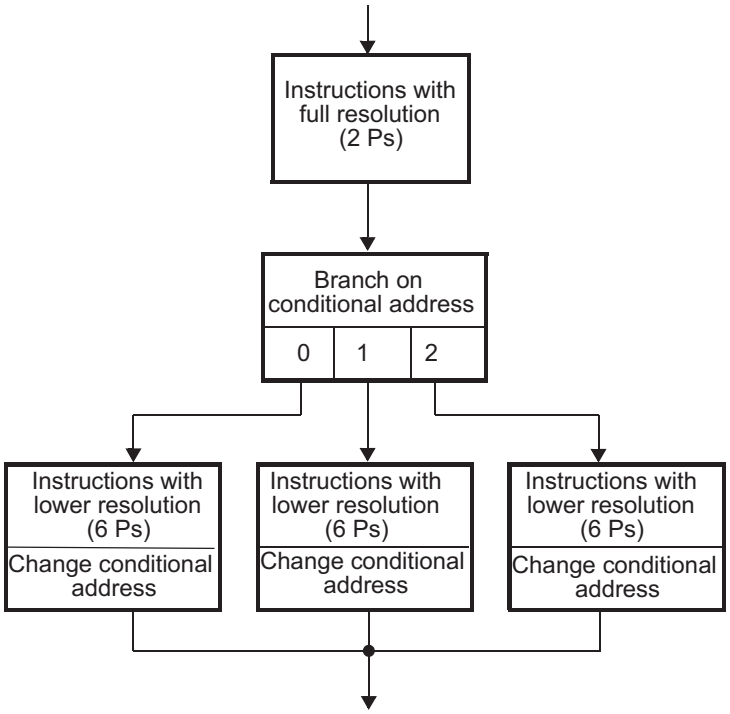
23.2.1.5 Architectural Restrictions on N2HET Programs

Certain architectural restrictions apply to N2HET programs:

1. The size of an N2HET program must be greater than one instruction.
2. An extra wait state is incurred by any instruction that modifies a field in the next instruction to be executed.
3. Only one instruction (using high resolution) is allowed per high resolution pin.
4. Consecutive break points are not supported. Instructions with break points must have at least a distance of two instructions (for example, at addresses 1, 3, 5, 7, and so on, assuming the program executes linearly)

NOTE: While it would be unusual to code an N2HET program that is only one instruction long, it is trivial to modify such a program to meet the requirement of restriction 1. Simply add a second instruction to the program, which may be a simple branch to zero.

To enforce restriction 3, the high resolution pin structures respond only to the first instruction that is executed matching their pin number with hr_lr=HIGH, regardless of whether or not the en_pin_action field is ON. Subsequent instructions are ignored by the high resolution pin structure for the remainder of the loop resolution period.



23.2.1.6 Multi-Resolution Scheme

The N2HET has the capability to virtually extend the counter width by executing instructions only once every N loop resolution periods. This decreases the timer resolution, but extends the counter range which may be useful when generating or measuring slow signals. Figure 23-5 illustrates how a multi-resolution scheme may be implemented in an N2HET program. An unconditional Branch instruction and an index sequence, using a MOV64 instruction in each low resolution loop, is required to control this particular program flow.

NOTE: HR instructions must be placed in the main (full resolution) loop to ensure proper operation.

Copyright © 2018, Texas Instruments Incorporated

Figure 23-5. Multi-Resolution Operation Flow Example

23.2.1.7 Debug Capability

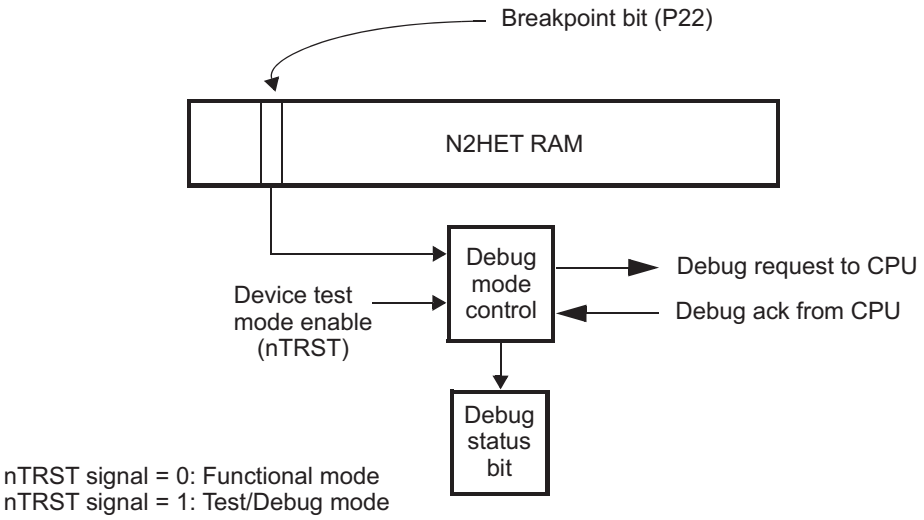
The N2HET supports breakpoints to allow you to more easily debug your N2HET program. Figure 23-6 provides an illustration of the breakpoint mechanism.

The steps to enable an N2HET breakpoint are:

1. Make sure the device nTRST pin is high, since N2HET breakpoints are disabled whenever this pin is low. (Normally this is handled automatically when a JTAG debugger is attached).
2. Attach a JTAG debugger and connect to the device that has been already programmed with the N2HET code that needs to debugged. (downloading to on-chip flash is outside the scope of this section).
3. Execute the CPU program at least until the point where the N2HET program RAM has been initialized by the CPU.
4. Open a memory window in the N2HET registers.
5. Make sure HETEXC2.DEBUGSTATUSFLAG bit is cleared.
6. Open a memory window on the N2HET RAM
7. Set bit 22 in the program field of the instruction(s) on which you wish to break. Note that this instruction will be executed **before** the N2HET is halted - slightly different from how CPU breakpoints behave.
8. Make sure the CPU and N2HET are running, if they are halted then restart the CPU through the JTAG emulator (N2HET will start when the CPU starts).
9. Both the CPU and N2HET will halt when breakpoint is reached.

When the N2HET is halted, its state machines are frozen but all of the N2HET control registers can be accessed through the JTAG emulator interface.

The current N2HET instruction address can be inspected by reading the HETADDR register; this should be pointing to the instruction that caused the breakpoint.



Copyright © 2018, Texas Instruments Incorporated

The N2HET internal working registers (A,B,R,S,T) are not directly visible through the JTAG emulator interface. If the content of these registers needs to be inspected, it is best to add an instruction like MOV32 which copies the register value to the N2HET RAM. This RAM location can be inspected when the N2HET halts.

To restart execution of both the CPU and the N2HET from the halted state:

1. Clear HETEXC2.DEBUGSTATUSFLAG bit.
2. Clear bit 22 in the program field of the instruction on which the breakpoint was reached.
3. Restart the CPU through the normal JTAG emulator procedure ('Run' or 'Go'). The N2HET will automatically start executing when it sees that the CPU has exited the debug state.

Figure 23-6. Debug Control Configuration

NOTE: Consecutive break points are not supported. Instructions with break points must have at least a distance of two instructions (for example, at N2HET addresses 1, 3, 5, 7, and so on)

23.2.2 N2HET RAM Organization

The N2HET RAM is organized into two sections. The first contains the N2HET program itself. The second contains parity protection bits for the N2HET program.

Each N2HET instruction is 96-bits wide but aligned to a 128-bit boundary. Instructions consist of three 32-bit fields: Program, Control, and Data. Instructions are separated by a fourth unimplemented address to force alignment to 128-bit boundaries.

The integrity of the N2HET program can be protected by Parity. Parity protection is enabled through the N2HET Parity Control Register (HETPCR).

Table 23-1 shows the base addresses for N2HET RAM and N2HET Parity RAM.

Table 23-1. N2HET RAM Base Addresses

N2HET1 Base Address	N2HET2 Base Address	Memory
0xFF46_0000	0xFF44_0000	N2HET Instruction RAM (Program/Control/Data)
0xFF46_2000	0xFF44_2000	N2HET Parity RAM

Copyright © 2018, Texas Instruments Incorporated

23.2.2.1 N2HET RAM Banking

Because the CPU must make updates to the N2HET RAM while the N2HET is executing, for example to update the duty cycle value of a PWM, it is important to understand how the N2HET RAM organization facilitates simultaneous accesses by both the HOST CPU and the N2HET.

The N2HET RAM is implemented as 4 banks of 96-bit wide two port RAM. This means that there a total of 8 ports available; four read and four write. Normally the N2HET will use up to two of these ports at a time. One read port is used to allow the N2HET to prefetch the next N2HET instruction while a write port may be used to update the data or control fields that have changed as a result of executing the current instruction.

N2HET accesses to its own internal RAM are given priority over accesses from an external host (CPU or DMA), this makes N2HET program execution deterministic which is a critical requirement for a timer.

Most N2HET instructions execute in a single cycle. Cases where a wait state impacts the N2HET program execution time are:

- The current N2HET instruction writes data back to the next N2HET in the execution sequence.
- The external host reads from an N2HET instruction where the automatic read-clear option is set, while the N2HET is executing from/on the same address (See Section 23.2.4.3).

Except for the case of automatic read-clear, the external host is stalled when the host and N2HET have a bank conflict. However this will typically only result in a stall of one cycle, due to the N2HET bank ordering which is organized on the N2HET Address least significant bit boundaries (See Table 23-2).

Assuming most of the N2HET program executes linearly through the N2HET Address space; if a bank conflict does exist it is usually resolved in the next cycle as the N2HET program moves to the next bank. N2HET programmers should avoid writing a program that accesses the same bank of N2HET RAM on every cycle, as this could lock the external host out of the N2HET memory completely.

Table 23-2 describes the N2HET memory map, as viewed by the N2HET as well as from the memory space of the host CPU and DMA.

Table 23-2. N2HET RAM Bank Structure

N2HET Address	Host CPU or DMA Address Space				
Instruction	Program Field Address	Control Field Address	Data Field Address	Reserved Address	N2HET RAM Bank
000h	XX0000h	XX0004h	XX0008h	XX000Ch	A
001h	XX0010h	XX0014h	XX0018h	XX001Ch	B
002h	XX0020h	XX0024h	XX0028h	XX002Ch	C
003h	XX0030h	XX0034h	XX0038h	XX003Ch	D
004h	XX0040h	XX0044h	XX0048h	XX004Ch	A
:	:	:	:	:	:
03Fh	XX03F0h	XX03F4h	XX03F8h	XX03FCh	D
040h	XX0400h	XX0404h	XX0408h	XX040Ch	A
:	:	:	:	:	:
1FFh	XX1FF0h	XX1FF4h	XX1FF8h	XX1FFCh	D

NOTE: The external host interface supports any access size for reads, but only 32-bit writes to the N2HET RAM are supported. Reserved addresses should not be accessed, the result of doing so is indeterminate.

Copyright © 2018, Texas Instruments Incorporated

23.2.2.2 Parity Checking

The N2HET module can detect parity errors in N2HET RAM. As described in Section 23.2.2 the N2HET allows 32-bit writes only. Therefore N2HET RAM parity checking is implemented using one parity bit per 32-bit field in N2HET RAM.

Even or odd parity selection for N2HET parity detection can be configured in the system module. Parity calculation and checking can be enabled/disabled by a 4-bit key in HETPCR.

During a read access to the N2HET RAM, the parity is calculated based on the data read from the RAM and compared with the good parity value stored in the parity bits. The parity check is performed when the N2HET execution unit makes a read access to N2HET RAM, but also when a different master (for example, CPU, HTU, DMA) performs the read access. If any 32-bit-word fails the parity check then an error is signaled to the ESM module. The N2HET address, which generated the error is detected and is captured in HETPAR for host system debugging. The address is frozen from being updated until it is read by the bus master.

The N2HET execution unit reads the instructions, which are 96-bit wide. They contain the program-, control- and data-field whereby each is 32-bit wide. So when fetching N2HET instructions parity checking is performed on three words in parallel.

If a parity error is detected in two or more words in the same cycle then only one address (word at the lower address) is captured. The captured N2HET address is always aligned to a 32-bit word boundary.

During debug, parity checking is still performed on accesses originating from the on-chip host CPU and DMA. However, parity errors that are detected during an access initiated by the debugger itself are ignored.

23.2.2.3 Parity Error Detection Actions

Detection of a N2HET parity error causes the following actions:

1. An error is signaled to the ESM module.
2. The Parity Address Register (HETPAR) is loaded with the address of the faulty N2HET field.
3. N2HET execution immediately stops. (The instruction that triggered the parity error is not executed.)
4. The Turn-On/Off-Bit in the N2HET Global Configuration Register (HETGCR) is automatically cleared.
5. All N2HET internal flags are cleared.
6. All N2HET pins selected by N2HET Parity Pin Register (HETPPR) enter a predefined safe state.
7. Register HETDOUT is also updated to reflect changes in pin state due to HETPPR.

The safe state for N2HET pins selected through the HETPPR register depends on how the pin is configured in the HETDIR, HETPDR, and HETPSL registers. Table 23-3 explains how the safe state is determined.

Table 23-3. Pin Safe State Upon Parity Error Detection

Safe State	HETDIR	HETPDR	HETPSL
Drive Low	1	0	0
Drive High	1	0	1
High Impedance	1	1	x

Copyright © 2018, Texas Instruments Incorporated

23.2.2.4 Testing Parity Detection Logic

To test the parity detection logic, the parity RAM has to be made accessible to the CPU in order to allow a diagnostic program to insert parity errors. The control register bit HETPCR.TEST must be set in order to make the parity RAM accessible. Once HETPCR.TEST is set, the parity bits are accessible as described in Table 23-4.

Each 32-bit N2HET field has its own parity bit in the N2HET Parity RAM as shown in Table 23-4. There are no parity bits for the reserved fields, since there is no physical N2HET RAM for these fields.

Table 23-4. N2HET Parity Bit Mapping

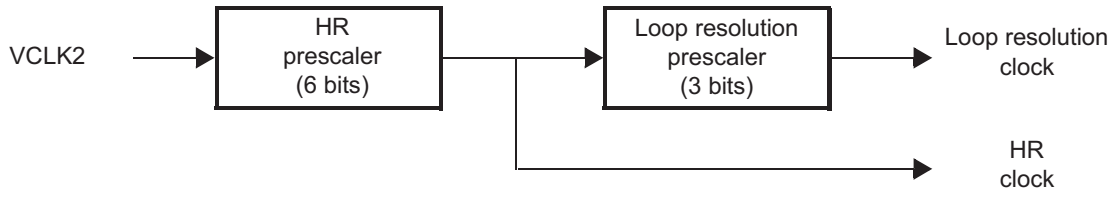
Address N2HET1	Address N2HET2	Bits	
		[31:1]	[0]
0xFF46_2000	0xFF44_2000	Reads 0, Writes have no effect	Instruction 0 Program Field Parity Bit
0xFF46_2004	0xFF44_2004	Reads 0, Writes have no effect	Instruction 0 Control Field Parity Bit
0xFF46_2008	0xFF44_2008	Reads 0, Writes have no effect	Instruction 0 Data Field Parity Bit
0xFF46_200C	0xFF44_200C	Reads 0, Writes have no effect	Read 0
0xFF46_2010	0xFF44_2010	Reads 0, Writes have no effect	Instruction 1 Program Field Parity Bit
....	....	...	...

23.2.2.5 Initialization of Parity RAM

After device power up, the N2HET RAM contents including the parity bits cannot be guaranteed. In order to avoid false parity failures due to the random state in which RAM powers up, the RAM has to be initialized.

Before initializing the N2HET RAM, enable the N2HET parity logic by writing to HETPCR. Then the N2HET Instruction RAM should be initialized. With parity enabled, the N2HET parity RAM will be initialized automatically by N2HET at the same time that the N2HET instruction RAM is initialized by the CPU. Note that loading the N2HET program with parity enabled is also effective.

Another possibility to initialize the N2HET memory and its parity bits is, to use the system module to start the automatic initialization of all RAMs on the microcontroller. The RAMs will be initialized to ‘0’. Depending on the even/odd parity selection, the parity bit will be calculated accordingly.



23.2.3 Time Base

All N2HET timings are derived from VCLK2 (see Figure 23-7). Internally N2HET instructions execute at the VCLK2 rate; but the timer loop clock and the high-resolution hardware timer clock can be scaled down from VCLK2. Two prescalers are available to adjust the timer loop resolution clock for the program loop, and the high resolution (HR) clock for the HR I/O counters.

- **Time Slots:** The number of cycles available for instruction execution per loop. Time Slots is the number of VCLK2 cycles in a Loop Resolution Clock.
- **High Resolution Clock:** The high resolution clock is the smallest time increment with which a pin can change it’s state or can be measured in the case of input signals. A 6-bit prescaler dividing VCLK2 by a user-defined HR prescale divide rate (hr) stored in the 6-bit HR prescale factor code (HETPFR). See Table 23-5.
- **Loop Resolution Clock:** The loop resolution clock defines the timebase for executing all instructions in a N2HET program. Since instructions can be conditionally executed, the longest path through the N2HET program must fit into one loop resolution clock period (LRP).A 3-bit prescaler dividing the HR clock by a user-defined loop-resolution prescale divide rate (lr) stored in the 3-bit loop-resolution prescale factor code (HETPFR). See Table 23-5.

Figure 23-7. Prescaler Configuration

The following abbreviations and relations are used in this document:

1. hr: high resolution prescale factor (1, 2, 3, 4,..., 63, 64)
2. lr: loop resolution prescale factor (1, 2, 4, 8, 16, 32, 64,128)
3. ts: Time slots (cycles) available for instruction execution per loop. ts = hr x lr
4. HRP = high resolution clock period HRP = hr × T_{VCLK2} (ns)
5. LRP = loop resolution clock period LRP = lr × HRP (ns)

The loop resolution period (LRP) must be selected to be larger than the number of Time slots (VCLK2 cycles) required to complete the worst-case execution path through the N2HET program. Otherwise a program overflow condition may occur (see Section 23.2.1.4). Because of the relationship of time slots to the hr and lr prescalers as described in item 3 above, increasing either hr or lr increases the number of time slots available for program execution. However, lr would typically be increased first, since increasing hr results in a decrease in timer resolution since it reduces the clock to the High Resolution IO structures.

The divide rates hr and lr can be defined in the HETPFR register. Table 23-5 lists the bit field encodings for the prescale options.

Table 23-5. Prescale Factor Register Encoding

LRPFC - Loop Resolution		HRPFC - High Resolution	
HETPFR[10:8]	**Prescale Factor lr**	**HETPFR[5:0]**	**Prescale Factor hr**
000	/1	000000	/1
001	/2	000001	/2
010	/4	000010	/3
011	/8	000011	/4
100	/16	:	:
101	/32	111101	/62
110	/64	111110	/63
111	/128	111111	/64
